Fibrinogen Test, Modification of Andersch and Gibson¹

Reagents.—

0.9% Sodium Chloride Solution, made by dissolving 9 gm. of sodium chloride in distilled water and diluting to 1,000 c.c. with distilled water.

0.25% Calcium Chloride, made by dissolving 250 mg. calcium chloride in distilled water in a 100 c.c. volumetric flask and diluting to 100 c.c. with distilled water.

10% Sodium Hydroxide. Use 10 gm. NaOH per 100 c.c. total volume.

20% Sodium Hydroxide. Use 20 gm. NaOH instead of 10 gm.

Standard Tyrosin Solution. Add 250 mg. tyrosin to about 50 c.c. of N/10 hydrochloric acid in a 100 c.c. volumetric flask and dilute to 100 c.c. with N/10 HCl.

Phenol Reagent of Folin and Ciocalteu (page 305).

Technic.—

Place 25 c.c. of 0.9% sodium chloride solution in a test tube and add 1 c.c. plasma. Mix and add 2 c.c. of 0.25% calcium chloride, placing a small stirring rod in the mixture, and allowing it to stand for one hour. Remove stirring rod containing fibrin and wash with distilled water.

Unknown

Place stirring rod in small tube and add 0.5 c.c. of 10% sodium hydroxide.

Place in boiling water for 30 minutes.

Cool and add 7.5 c.c. distilled water.

Standard

Place 2 c.c. standard tyrosin solution in a large test tube and add

5.5 c.c. of distilled water

and 0.5 c.c. of 10% sodium hydroxide.

Add to both unknown and standard 1 c.c. phenol reagent

and 3 c.c. of 20% sodium hydroxide solution. Mix and read in a colorimeter after 30 minutes.

Calculation.—

$10/R \times 100 \times 0.5 \text{ mg.} \times 13 = \text{mg. fibrinogen in 100 c.c. plasma.}$

Range of fibrinogen is 350 to 750 mg. per 100 c.c. plasma.

Anticoagulant Therapy

Dicumarol (bishydroxycoumarin) (3,3'-methylenebis-4-hydroxycoumarin) has been well established as an adjunct in the management of thromboembolic disease. Perhaps its most universal application in clinical medicine has been in acute coronary thrombosis as a prophylactic against extension of the thrombus. Coronary occlusion has been known to be associated with the formation of mural thrombi which may serve as a nidus for emboli. Prophylactic administration of Dicumarol reduces the incidence of emboli considerably. There is

general agreement that dicumarolization reduces the mortality from acute coronary occlusion but some difference of opinion as to what extent. There is sufficient question about the effect on mortality as to reflect on the wisdom of routine use of anticoagulant therapy in myocardial infarction.

Schnur² studied the case records of 1,350 patients with myocardial infarction and found the mortality ranged from 8 per cent in the mildest cases to 95 per cent in the severest cases. He attempted to correlate a great number of variables, giving a rating ("pathologic index") to all cases. He could find no difference in the mortality rates between patients treated with or without anticoagulants, and he found that mortality rates could be predicted on the pathologic index. Furman and associates³ compared a group of 100 patients who received Dicumarol with a group of 211 patients with coronary occlusion who were not treated with anticoagulants. Using various criteria for rating, they established three classes of patients: (a) "good risks," (b) "poor risks," and (c) "very poor risks." In the "good risk" group, there was no significant difference in mortality between those treated with anticoagulants (2 per cent mortality) and those untreated (1.3 per cent mortality). The same was true of the "very poor risks" in whom the mortality rate was over 98 per cent, regardless of treatment. In the intermediate group, "poor risks," there appeared to be some significant difference favoring anticoagulant therapy, with 23 per cent mortality in the treated as compared with 41 per cent mortality in the untreated cases. In this "poor risk group," beneficial results of anticoagulant therapy were greatest in those patients having their first attack of coronary occlusion. Russek and Zohman⁴ sent a questionnaire to several hundred physicians listed in the *Directory of Medical Specialists* relative to the use of anticoagulant therapy in myocardial infarction. Over 50 per cent of those replying to the questionnaire stated that they do not use anticoagulants routinely.

Wright and co-workers⁵ have fully analyzed the findings of a cooperative study of the use of anticoagulants in 1,031 cases of definitely diagnosed coronary thrombosis. Twenty-six per cent of the control subjects developed thromboembolic complications as compared with only 11 per cent in the patients treated with anticoagulants. This included venous thromboses and intracardiac complications as well as cerebral, visceral, and peripheral emboli. They found that thromboembolic phenomena were more likely to occur in the following patients: (1) severely ill, (2) 10 per cent or more overweight, (3) older age groups, (4) those having previous history of thromboembolic phenomena, (5) heart failure or shock, and (6) auricular fibrillation or heart block. These patients are, therefore, particularly in need of anticoagulant therapy. Since no control subgroup showed a lower incidence of thromboembolic phenomena than treated patients, these authors conclude that anti-

⁵Wright, I. S., Marple, C. D., and Beck, D. F.: *Myocardial Infarction: A Study of 1,031 Cases, Its Clinical Manifestations and Treatment With Anticoagulants*, New York, 1954, Grune & Stratton.

coagulant therapy should be used in "all cases, including mild ones, where positive contraindications do not exist and adequately controlled anticoagulant therapy is feasible."⁶

Wright and co-workers report that mortality statistics do not show as striking a difference as do thromboembolic phenomena when anticoagulant therapy is used, but here again the differences tend to favor the use of anticoagulants. In the control group, 23.4 per cent died as compared with 16 per cent in the treated group. However, thromboembolic phenomena had an incidence of 42 per cent in the control and only 23 per cent in the treated groups that died. If one limits the statistics to the period of potentially effective anticoagulant therapy (the fourth day of therapy through four days after the last dose), only 9.5 per cent of the treated patients died as compared with 17.4 per cent of the control group during a corresponding period. When subclasses were studied, there were found substantial reductions with anticoagulant therapy in fairly much the same groups as those prone to thromboembolic phenomena. "The findings do not support the policy recommended by some of treating only patients appearing severely ill at onset and deferring anticoagulant therapy in milder cases until complications occur."⁷ An important feature is that even though *mortality* in good risk cases is less than 2 per cent, whether treated or untreated, the former showed only nine thromboembolic complications per hundred in contrast with twenty-nine per hundred cases in the latter.

Wright's group comes to the conclusion that all patients with myocardial infarction should receive anticoagulant therapy unless a contraindication to such therapy exists.

Schnur,⁸ in a question-answer address, read in a panel discussion on the use and abuse of anticoagulant therapy, points out that not all of the problems relating to such therapy are readily solved. He particularly indicates the difficulties of the clinical diagnosis of thromboembolism and even questions whether post-mortem examinations can fully reflect this feature or mural thrombi. He believes that the effective ranges of prothrombin at present are at best "educated guesses." His position is that of selective therapy rather than routine. This subject is pursued further by Russek and Zohman⁹ who conclude that "anticoagulant therapy is neither necessary nor desirable for the large segment of patients who sustain their first attack of acute myocardial infarction and present no unfavorable criteria for recovery at the time of the first examination."

Everyone is agreed that the use of anticoagulant therapy is based on a reduction of prothrombin time by Dicumarol and related drugs. Serial determination of the prothrombin time is the only adequate method of control of such therapy and there is no substitute known at present for such control. For this reason, anticoagulant therapy with Dicumarol and related compounds (Tromexan, Link's compound 63, Danilone) should not be considered unless daily prothrombin time determinations are available. The clinical picture, bleeding times, clotting times, and other clinical laboratory procedures for

⁶Modern Concepts of Cardiovascular Disease, Am. Heart A. 23: 208, 1954.

⁷Wright, I. S., et al., loc cit.

studying the coagulation status of patients are totally inadequate and should not be considered as tools for measuring control of therapy. The purpose of rigid control is twofold; namely, (1) reaching and maintaining effective levels, and (2) avoiding the complication of hemorrhage. Wright and associates found a level of 11 to 23 per cent prothrombin activity as the optimal range for therapeutic effect, and when this range was achieved, thromboembolic phenomena were at their lowest incidence. Prothrombin percentages lower than this range produced no added advantages. Their rule of thumb was a prothrombin time which was two and one-half times the control if the latter were 12 to 18 seconds. If dosage is inadequate and optimal levels are not achieved, benefits will be minimal.

Hemorrhage is the only known complication of Dicumarol therapy and occurs at prothrombin levels of 10 per cent or less. In uncontrolled cases, hemorrhage may be fatal or reach serious proportions. In cases controlled by daily prothrombin times, hemorrhage is generally insignificant. The most common clinical manifestations of hemorrhage are hematuria, hemoptysis, hematemesis, and epistaxis. Bleeding from other sources may occur and in the uncontrolled cases may involve any organ system in the body. The occurrence of hemorrhagic phenomena is a signal for cessation of anticoagulant therapy, careful following of the prothrombin time, and an indication for active treatment to restore the value toward a safe level. The treatment consists of administration of water-soluble vitamin K in a dose of 60 to 72 mg. intravenously once or twice. In the presence of severe bleeding, 250 to 500 mg. of vitamin K₁ oxide orally is recommended. Transfusions of whole fresh blood or plasma may be necessary in cases associated with severe hemorrhage. Transfusions should be considered not only to re-establish the prothrombin status but may be necessary to correct the anemia resulting from blood loss.

There is considerable difference of opinion as to the method of choice in prothrombin determinations. In clinical practice, the aim is relative simplicity with good control. A critical survey of the present knowledge of this procedure leaves us with the impression that oversimplicity is nigh impossible if one is to achieve really good control. The modified dilution methods (modified Quick, Shapiro-Link, or the "P and P" test of Owren) appear to answer the problem of adequate laboratory control. The literature covering methods and materials is so voluminous that a review of this aspect alone would be impossible here. Suffice it to say that whatever technic is employed, certain basic principles must be adhered to; namely, (1) that the technic be followed scrupulously as directed by the author of the technic, (2) materials be assayed carefully for potency, and (3) controls be included in any determination. Perhaps some of the differences in clinical results are reflections of poor laboratory control rather than an index of failure of anticoagulant therapy. One objection to insistence on such high standards of laboratory control is that hospitalization becomes almost imperative in order to achieve this. The resultant economic strain on hospitalized patients is used as an argument against routine anticoagulant therapy. However, in disease as serious as coronary occlusion, it is somewhat difficult to argue against this care, except perhaps in the mildest cases. Wright¹⁰ argues against withholding anticoagulants be-

¹⁰Wright, I. S.: *Circulation* 5: 161, 1952.

cause it is impossible to predict which cases might develop thromboembolic phenomena. He states that "unfortunately such prophetic vision foresight has failed. It is more difficult to predict whether the course of a case will be mild or severe on the day of onset, when decisions regarding therapy must be made, than in retrospect, after the patient has been discharged from the hospital. If a physician waits until the first thromboembolic episode occurs, he may have a permanently disabled patient, as in the case of a hemiplegia due to an embolus to the brain, or a dead one."

Dicumarol dosage is determined by routinely estimating the prothrombin activity prior to the initial dose. If the prothrombin time test is relatively normal, then the following dosage schedule is recommended¹¹:

First day: Give one dose of 200 to 300 mg. orally, depending on the size and condition of the patient.

Second day: Determine prothrombin time and if activity is more than 25 per cent, give 100 to 200 mg. of Dicumarol.

Third and each subsequent day: Determine prothrombin time and administer dosage based on previous experience with the patient. If the prothrombin activity is greater than 25 per cent, administer 50, 100, or 200 mg. as previous response indicates.

Wright recommends continuation of therapy for approximately 4 weeks in patients with coronary occlusion. If for any reason Dicumarol therapy has been discontinued and there occurs an indication for re-instituting therapy, treatment must be based on the same controls as originally used. Dosages are guided by the patient's previous response and daily prothrombin activity determinations. There is apparently no sensitivity to the drug, and resistance occurs only if vitamin K₁ therapy has been recently used. Either larger doses of Dicumarol may be necessary or heparin may have to be added to the anticoagulant regimen. If patients on anticoagulants require surgery for any reason whatsoever, the prothrombin time should be returned to normal before surgery to avoid hemorrhage.

In addition to the use of anticoagulant therapy in coronary thrombosis, it is recommended in the following conditions:

1. Majority of cases of thrombophlebitis regardless of origin, including recurrent idiopathic thrombophlebitis, post-infectious, or post-traumatic. Wright¹² makes the interesting observation that a thrombophlebitis that progresses relentlessly despite adequate therapeutic levels of the coumarin compounds should arouse the suspicion of malignancy. He cites 20 examples of persistence of migratory phlebitis refractory to adequate therapy. Carcinoma of the pancreas and liver are most commonly associated with distant thrombophlebitis, although other organs may also have such association.

2. The prevention of postoperative thromboembolic disease. Although statistics generally show a lower incidence of postoperative thrombophlebitis or embolus¹³ in patients given prophylactic dicumarolization, there is some

¹¹Brochure on package information, Abbott Laboratories, North Chicago, Ill.

¹²Wright, I. S.: *Circulation* 5: 161, 1952.

¹³Wise, W. D., Loker, F. F., and Brambel, C. E.: *Surg., Gynec. & Obst.* 88: 486, 1949.

question as to the wisdom of such procedure *routinely*, and perhaps it should be reserved for selected cases in which there is a notoriously high incidence of postoperative thrombophlebitis, such as pelvic surgery.

3. Patients with acute embolic or thrombotic occlusion of the peripheral arteries from any of several causes.

4. Patients with recurrent embolization and auricular fibrillation, such as occurs in rheumatic heart disease.

5. Post-partum patients with previous histories of recurrent thrombophlebitis.

Dicumarol therapy should be used with caution in the following conditions:

1. Severe malnutrition and cachexia.

2. Unusually prolonged menses or menorrhagia.

3. Patients with reduced prothrombin activity due to salicylates or para-aminosalicylic acid in large doses. If Dicumarol therapy appears of greater value in treating a particular patient, it is recommended withholding large dosages of these drugs which can of themselves reduce the prothrombin activity.

4. Patients under prolonged antibiotic or sulfonamide therapy in which changes in the intestinal flora affect vitamin K synthesis.

5. Severe hypertension.

6. In any patient with an initial lowered prothrombin activity unless the cause for such lowering can be well delineated and in itself does not constitute a contraindication to anticoagulant therapy.

7. In patients recently subjected to operations on the central nervous system.

8. In patients with fever. Animal experiments have shown an accentuated response in the presence of fever.

The contraindications to anticoagulant therapy are:

1. *Inadequate facilities for prothrombin determinations.*

2. Patients with hemorrhagic diatheses, particularly where prothrombin is affected directly or indirectly as a result of the disease. Hemophilia-like syndromes and the thrombocytopenic purpuras are obvious examples of such diseases. In the thrombopenic states, the lowered platelet count may be primary or secondary. It is safe to say that any patient showing a defect of the coagulation mechanism should be eliminated from anticoagulant therapy.

3. Pregnancy in the second or third trimester.

4. Patients scheduled for immediate surgery.

5. Patients with moderately or fully advanced renal or liver disease.

6. Patients with jaundice due to biliary obstruction or hepatocellular disease.

7. Patients under continuous tube drainage of the stomach or small intestine.

8. Patients with hemorrhage of the central nervous system.

9. Patients with ulcerating lesions (gastrointestinal tract) and granulomatous lesions.

Since the introduction of anticoagulant therapy with Dicumarol, other drugs have been found and studied. Tromexan or 3,3'-carboxymethylene bis-(4-hydroxycoumarin) ethyl ester is a recent derivative and, as its chemical structure indicates, related to Dicumarol. Compound 63 of Link¹⁴ is a 4-hydroxycoumarin which has also been used in man and animals. Another group of anticoagulants which have come into more recent use are indanedione derivatives, such as Danilone* (2-phenyl-1,3-indanedione) and Indon† (2-phenyl-1,3-indanedione). These two related compounds have a more rapid effect on the prothrombin activity both in lowering the level and in returning it to normal after cessation of therapy. The hypoprothrombinemia induced by them is more refractory to vitamin K therapy than the coumarin derivatives. Excellent comparative studies of these newer anticoagulants are to be found in the *Fourth and Fifth Conferences on Blood Clotting of the Josiah Macy, Jr., Foundation*.¹⁵

Heparin and Postoperative Thrombosis and Embolism.—Crafoord and Jorpes of Stockholm, Sweden, utilized heparin in attempting to prevent postoperative vascular thrombosis. In 325 patients treated with heparin, no great complication occurred, whereas, in the control series of 1,111 similar cases, complications occurred in 9 per cent. In Sweden, 30,000 doses of heparin of 50 to 100 mg. each have been given intravenously without any fatalities or any noteworthy drawbacks.

Murray and Best found no thrombosis or embolism in 400 patients. Moreover, patients with phlebitis were improved by treatment with heparin, and favorable effects of heparin in a small number of cases of pulmonary embolism were reported.

Heparin is an anticoagulant used alone or in conjunction with the aforementioned anticoagulants. Its action is a direct one on the coagulation mechanism and does not affect the prothrombin activity of blood. Its action is followed by determination of the clotting time and not by prothrombin time determinations.

BLOOD FINDINGS IN VARIOUS DISEASES

THE ANEMIAS

The term "anemia" is a clinical conception, which was used originally to designate a decrease in the total quantity of blood. It is now applied much more frequently to diseases accompanied by a decrease in the number of erythrocytes or hemoglobin content or both.

Classification of the Anemias

Wintrobe¹⁶ grouped the anemias on the basis of the absolute constants of the red cells and hemoglobin. This classification is as follows: (1) macrocytic anemia; (2) normocytic anemia; (3) simple microcytic anemia, and (4) hypochromic anemia.

Chronic blood loss Deficient intake, absorption, or metabolism of iron Prematurity Hereditary leptocytosis	Secondary anemia, hypoferric anemia, achromic anemia, simple anemia, iron deficiency anemia
Trait With erythrocytosis Pernicious anemia, type <i>macrocytic anemia</i> , due to Unknown cause	Cooley's anemia, thalassemia, erythroblastic anemia, Mediterranean anemia, disease, or fever, target cell anemia, familial microcytic anemia, hereditary or familial poikilocytosis
Infantile Pernicious anemia	Achrestic anemia, idiopathic refractory megaloblastic anemia
Pregnancy	Megaloblastic anemia of infancy Addisonian anemia, Biermer's disease, primary anemia, macrocytic anemia, hyperchromic anemia, megalocytic anemia, megaloblastic anemia, "Severe" anemia of pregnancy, primary anemia of pregnancy, hemolytic anemia of pregnancy, macrocytic anemia of pregnancy
Sprue Tropical	Indische Sprue, psilosis, aphthae tropicae, tisis intestinal, Cochín-China diarrhoea
Nontropical Nutritional deficiency Celiac disease Chronic intestinal obstruction Diphyllobothriasis Gastrectomy Disturbance in continuity of the gastrointestinal tract Tuberculous enteritis	Idiopathic steatorrhea, Gee-Herter disease Goat's milk anemia, tropical macrocytic anemia
<i>Macrocytic anemia</i> , due to Unknown cause Hypoplasia Liver disease	Achrestic anemia

On this basis of classification, under the macrocytic normochromic anemias would be included pernicious anemia, sprue, and the so-called pernicious anemia of pregnancy. The normocytic normochromic anemias would include those which follow acute hemorrhage and aplastic anemia. The microcytic normochromic anemia is the type that occurs in various infections and intoxications, while under hypochromic microcytic anemia there would be included the anemias in which there is marked chronic blood loss or iron deficiency.

Anemias may be due to disturbances in the bone marrow function. **Acute loss of blood** produces an anemia which persists until restitution through active bone marrow function. First there occurs in the circulating blood a flooding of young forms, and perhaps a leukocytosis due to the proliferation of the myeloid system. There is, of course, present in the blood of these individuals after an acute loss of blood hemoglobin-poor immature red cells. There is a lowered color index. There is necessarily a reparative polycythemia. Erythropoiesis continues, the cells approach closer to the normal, and the red blood cell count, which has been elevated by reason of the accelerated bone marrow function, becomes lower, and the color index approaches 1.

As a result of infectious diseases, the bone marrow function is disturbed by the toxin. This is followed by an anemia. There is an anemia seen in typhus, polyarthritis, and syphilis.

A more intense anemia is seen in connection with **malignant tumors**. We find a very severe grade of anemia in carcinoma of the esophagus and stomach. **Chemical substances**, such as lead, mercury, nitrobenzene, benzol, when ingested all produce an anemia.

We have elsewhere alluded to the basophilic punctation seen in lead poisoning. This condition is the result of the toxic effect upon bone marrow erythropoiesis. Further etiological factors in anemia are **intestinal parasites**, such as *Diphyllobothrium latum*, *Taenia*, and *Trichuris*. *Ancylostoma duodenale* and *Necator americanus* produce anemia by loss of blood.

Discussion of anemia due to the *Diphyllobothrium latum* has been carried on in medical literature for some time. The question that has agitated the writers on this subject is whether or not this fish tapeworm in disease causes the anemia which is so like a case of pernicious anemia or whether, as Magath² has stated, the presence of *Diphyllobothrium* is considered only as a "trigger" that sets off the illness. Schauman,³ the leading European investigator of this problem, maintains that *Diphyllobothrium* is capable of causing an anemia which is not distinguishable from true primary pernicious anemia, and that the reason the incidence of the disease is so small is that the "ordinary host is refractory toward the anemia-causing agent of the tapeworm." Piney⁴ has called attention to the close resemblance between this anemia and true primary pernicious anemia. He believes that this condition may be elicited in some by the toxins of the fish tapeworm but thinks a constitutional predisposition probably exists in these patients. Birkeland⁵ reviewed all the foreign as well as the American literature on *Diphyllobothrium* anemia, and,

⁵Birkeland, I. W.: Bothriocephalus Anemia, Medicine 11: 1, 1932.

after presenting the observations and opinions of apparently all who have written on this subject, in an unbiased but critical manner, concluded that the anemia occurring in symbiosis with an infestation by *Diphyllobothrium* is probably not due to any specific substance elaborated by this parasite but to a constitutional factor which would probably cause this type of patient to have a pernicious anemia without the presence of the parasite, granting that there occurs some unknown precipitating factor in this disease. In other words, he considers patients who suffer and survive *Diphyllobothrium* anemia as having had an abortive form of true primary pernicious anemia. Von Bonsdorff⁶ suggests that the pernicious anemia picture of *Diphyllobothrium*

Fig. 178.—Blood film, hypochromic anemia, showing hypochromia, poikilocytosis, and anisocytosis. ($\times 950$.)

infestation is due to two possible mechanisms. One involves the competition of parasite and host for vitamin B₁₂; in the event that the worm wins in this race, a deficiency develops in the host. An alternative, or contributory mechanism, is that intrinsic factor production may be diminished if the parasite is located high up in the small intestine. If the parasite moves lower down in the gastrointestinal tract, the pernicious anemia picture disappears.

Isaacs, Sturgis, and Smith studied a patient with a fish tapeworm infestation who had a typical blood and clinical picture of primary pernicious anemia which was amenable to liver therapy before removal of the tapeworm and who had no relapse of the anemia following the eradication of the parasite, even when liver therapy was stopped. Seyderhelm has demonstrated that the ground-up body of the fish tapeworm has a hemolytic action both in vitro and in vivo. Hunnicutt⁷ has given a report on a very interesting case of a native of Finland who had a disease which was singularly like true pernicious anemia and cleared up under liver therapy and who later showed

⁷Hunnicutt, Thos. N., Jr.: *J. A. M. A.* 104: 1984, 1935.

eggs and segments of the worm. After suitable therapy the worm was eliminated and the patient was discharged with a normal blood count; he remained normal after fourteen months, without a return of the anemia and with no specific therapy during this period. It would seem, according to this writer, that this was probably a case of a true tapeworm anemia.

Enterogenous anemias, due to **infectious septic processes**, particularly ulcerative colitis, produce a severe toxic anemia. **Chronic pyelitis** also produces severe anemia.

Hemolytic substances, such as potassium chlorate, purine, etc., when ingested, so disturb the red cells in the blood stream that there develops a hemoglobinemia and a hemoglobinuria. Attention must be called, too, to the high-grade anemia seen in **nephritis**. Nonnenbrouch⁸ believes this is due to hydremic plethora.

The "**proletariat**" anemia of Naegeli is a simple anemia traceable to lack of food. There is another type of simple anemia due to climatic conditions, the so-called "**tropical anemia**."

The **influence of light** upon the causation of anemia has been a subject of discussion. It is improbable that it has any effect. For instance, the long polar night, according to Nansen's figures, did not produce anemia as long as the nutritional state of the explorers was good.

Schoenenberger and Semple state that horses which have been kept underground ten to twenty years in mining and tunnel operations show no anemia.

Naegeli has shown that there are anemias produced through **disturbances in the internal secretory apparatus**.

Later there will be discussed some other forms of anemia referable to children (see Remarks on Hematology of Infants and Childhood).

Constitutional Hemorrhagic Anemia has been described by Gaesslen. In these cases, there are disturbances in development of the mandible, fingers, hands, sometimes microphthalmus, internal deformities, sclerosis, and muscle dystrophy. In these cases, there is usually a megalosplenism. This disease has baffled hematologists as to its origin. It is noteworthy that the children of these constitutional hemolytic anemic patients show the same disease, down to the third generation. Such patients show constitutional changes in the red cells and a marked change in the fragility test.

Idiopathic Hypochromic or Microcytic Anemia is a new development in the study of hematology. It is characterized by an absence of free hydrochloric acid in stomach contents in middle-aged women who have a microcytic type of red cell. These patients respond to iron just as the chlorotic patients do. The condition simulates chlorosis except that it occurs in middle age and there is no hydrochloric acid in the gastric contents. For further discussion of this very interesting condition, see the review by Wintrobe and Beebe.⁹

Figs. 179 to 191 by Haden graphically present the state of the bone marrow, peripheral blood, and related organs with their relative status in normal and various abnormal conditions related to the red blood cells. Study of these illustrations is highly remunerative when related to the discussion in the text.

⁸Nonnenbrouch: Arch. f. exper. Path. 91: 218, 1921.

⁹Wintrobe, M. M., and Beebe, R. T.: Idiopathic Hypochromic Anemia, Medicine 21: 187, 1933.

FORMATION

NORMAL ADULT

Red cells formed largely in ribs, skull and vertebrae
Total normal volume of marrow is 1400 cc. Normal color is greyish red
For red cell formation, non-specific substances necessary for all cells are required as well as two specific substances, iron and the erythrocyte maturing factor (E.M.F.)
One trillion cells and 25 gms HB formed each day
Rate of formation measured by reticulocyte percentage in circulation
Normal life of red cell about 30 days

CIRCULATION

Twenty-five trillion red cells in blood stream. Each cell during its life, makes 50,000 to 100,000 complete circuits from lungs to tissues. Functions as conveyor for hemoglobin which carries oxygen from lungs to tissues
Blood count represents balance between red cell and hemoglobin formation and destruction

EXAMPLE

RBC 50 Million
HB 100% (134 gms)
Volume Index 100 (90 cubic microns)
Color Index 100 (32 micromicrograms)
Saturation Index 100 (34.7%)
Icterus Index 46 units
Reticulocytes 0.5-10%

DESTRUCTION

Old red cells taken out by reticulo endothelial cells, largely those of spleen
1 trillion red cells destroyed each day
25 gms HB destroyed each day
100 mg. of iron released
65 mg. used again
15 mg. lost and replaced by food
500 cc. bile formed and excreted by the liver containing 300 to 400 mg. of bile pigment
Rate of destruction gauged by iron released and bile pigment formed
Only clinical laboratory measure is icterus index or quantitative Van den Bergh

Eighty-five percent of iron released returns to marrow to be used again

Fig. 179A.—Normal red cell physiology. The cells are being formed and destroyed at a constant rate. The cells vary little in volume and hemoglobin content. The rate of delivery of new cells is gauged by the reticulocyte count and the rate of destruction by the icterus index. The blood count and hemoglobin content show only the balance between the formation and destruction of red cells. *Editor's note:* Normal life of the red blood cells is 120 days instead of 30 days. (From Haden: Principles of Hematology, Lea & Febiger. Modified from Haden: J. Lab. & Clin. Med.)

FORMATION

No immediate change in marrow
Later becomes more active

CIRCULATION

← Blood Stream →

EXAMPLE

RBC 250
HB 50%
Volume Index 100
Color Index 100
Saturation Index 100
Icterus Index 3
Reticulocytes 1%

DESTRUCTION

Rate of hemoglobin destruction is immediately normal. Later is decreased

Fig. 179B.—The red cells after an acute hemorrhage. The cells are reduced in number but normal in size (volume index 1), and hemoglobin content (color index 1). (From Haden: Principles of Hematology, Lea & Febiger. Modified from Haden: J. Lab. & Clin. Med.)

Fig. 180.—The red cells in excessive destruction by a toxic substance (phenylhydrazine). The red cells are damaged and then rapidly removed from the circulation by the spleen so splenomegaly results. The high icterus index (25 units) is due to the accelerated destruction of hemoglobin. The high reticulocyte count (10.3 per cent) is an attempt on the part of the bone marrow to compensate for the abnormal destruction of cells. (From Haden: Principles of Hematology, Lea & Febiger. Modified from Haden: J. Lab. & Clin. Med.)

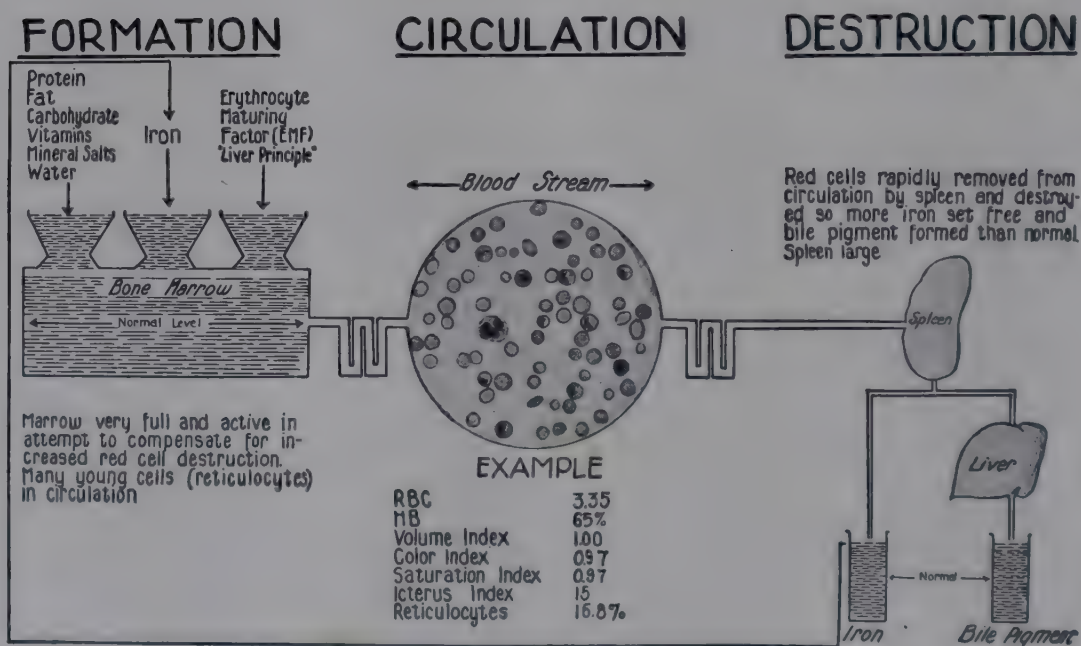

Fig. 181.—The red cells with excessive removal from the blood stream by the spleen because of spherocytic shape. In congenital hemolytic icterus the cells are abnormal in shape (spherocytes) and are rapidly removed from the circulation. The icterus index is high (15 units) due to the excessive destruction and the reticulocyte per cent is also high (15.8 per cent) indicating an excessive release of red cells from the marrow. In this condition the cells remain in the circulation only a few days as compared with a normal time of 120 days. (From Haden: Principles of Hematology, Lea & Febiger. Modified from Haden: J. Lab. & Clin. Med.)

Fig. 182.—The red cells in excessive removal from the blood stream by the spleen because of sickle shape. This is also a hemolytic anemia as shown by the increased icterus index and the reticulocytes. (From Haden: Principles of Hematology, Lea & Febiger. Modified from Haden: J. Lab. & Clin. Med.)

Fig. 183.—Red cells in anemia due to aplasia of marrow by myelotoxic agent as arsphenamine. Here the marrow is decreased in volume and few erythrocytes, leukocytes, or thrombocytes can be delivered. Such cells as are found are normal. (From Haden: Principles of Hematology, Lea & Febiger. Modified from Haden: J. Lab. & Clin. Med.)

Fig. 184.—The red cell in a quantitative depression of the bone marrow as by leukemia. Here the erythropoietic tissue is crowded out by the leukopoietic tissue so less cells than normal can be formed. Such cells as are formed are normal in volume and hemoglobin content. (From Haden: Principles of Hematology, Lea & Febiger. Modified from Haden: J. Lab. & Clin. Med.)

Fig. 185.—The red cell in a quantitative depression of the bone marrow as by nephritis. Here the amount of functioning tissue is not decreased but the rate of activity is much less than normal. Again the cells formed are normal in volume and hemoglobin contents. (From Haden: Principles of Hematology, Lea & Febiger. Modified from Haden: J. Lab. & Clin. Med.)

Fig. 186.—Red cells in an anemia due to an idiopathic deficiency in the erythrocyte-maturing factor (pernicious anemia). Here the marrow is hyperplastic because the cells which cannot be normally completed accumulate. Such cells as are released are not normal as shown by the macrocytosis (volume index 1.29) which indicates a deficiency of the specific-maturing factor (EMF). Many cells die in the marrow, since they are not normally released, so the bile pigment content is increased (icterus index, 10 units). (From Haden: Principles of Hematology, Lea & Febiger. Modified from Haden: J. Lab. & Clin. Med.)

Fig. 187.—The red cells with a deficient intake of iron. As a result of the chronic iron deficiency, the hemoglobin is reduced (color index 0.63) and the cells become smaller (volume index 0.75). The icterus index is low because less hemoglobin is destroyed. The reduction in number of cells is much less than in hemoglobin. (From Haden: Principles of Hematology, Lea & Febiger. Modified from Haden: J. Lab. & Clin. Med.)

Fig. 188.—The red cells with chronic bleeding. Here there is a chronic iron deficiency so the picture is exactly like that with a deficient intake of iron (Fig. 187). (From Haden: Principles of Hematology, Lea & Febiger. Modified from Haden: J. Lab. & Clin. Med.)

Fig. 189.—The red cells in a qualitative depression of the marrow in which the erythrocyte-maturing factor is not normally used. Here the marrow receives the specific factor but cannot use it. The picture is similar to that with an idiopathic defect in formation of the necessary factor (Fig. 186). (From Haden: Principles of Hematology, Lea & Febiger. Modified from Haden: J. Lab. & Clin. Med.)

Fig. 190.—The red cells in a qualitative depression of the marrow in which iron cannot be used. Here the marrow receives iron but cannot incorporate it normally so the picture is similar to that due to an insufficient supply of iron (Figs. 187 and 188). (From Haden: Principles of Hematology, Lea & Febiger. Modified from Haden: J. Lab. & Clin. Med.)

Fig. 191.—The red cells in polycythemia vera. In this disease there is an enormous overproduction of erythrocytes so the marrow is filled with erythrogenic tissue. The rate of destruction does not keep pace with red cell formation and the blood volume increases. The increase in red cells per unit volume and in blood volume gives a great increase in red cell mass. (From Haden: Principles of Hematology, Lea & Febiger. Modified from Haden: J. Lab. & Clin. Med.)

Hemorrhagic and Posthemorrhagic Anemia

Immediately following the hemorrhage there is a drop in the red count and the hemoglobin. Certain changes in the blood picture are of importance in estimating the extent of the hemorrhage and the amount of attempted regeneration on the part of the erythropoietic and leukopoietic systems.

A rapidly rising erythrocyte count, that is, a constant rise if counts are taken hourly or periodically during the day, denotes a possible hemoconcentration leading to shock.

Leukocytosis with neutrophilia and no shift is seen following hemorrhages. In severe hemorrhage there is a slight left shift. In exhausting hemorrhages there is a regenerative shift.

Marked polychromasia in the blood film (rise in reticulocytes) indicates regeneration of the erythrocytes and is a good sign following a hemorrhage. Basophilic punctation means degenerative effects, possibly toxic, on the erythrocytes. An occasional normoblast can be found in the blood in severe hemorrhages as a sign of rapid regeneration of the erythrocytes, but if many normoblasts appear, there is overstimulation of the erythropoietic system and this is regarded unfavorably. Megaloblasts are serious findings.

Blood platelets rise rapidly following a hemorrhage as a sign of regeneration of the erythrocytes. Schilling regarded this rise as proof of his theory that blood platelets represent altered forms of the nuclei of erythrocytes which are extruded as the erythrocytes leave the bone marrow. The rise in blood platelets, according to Schilling, corresponds mathematically to the number of newly formed erythrocytes which enter the blood stream following a hemorrhage.

The erythrocyte count and hemoglobin figures are used as gauges in determining whether or not transfusions are indicated, and the amount of blood to be administered.

The erythrocytes often belong to the classification microcytic hypochromic or normocytic normochromic.

Chlorosis

Chlorosis is a very interesting disease frequently seen in young women, although Castle and Minot¹ state: "At present it is very rarely observed at least in the form described in the medical literature of the preceding three centuries. Undoubtedly cases of hypochromic anemia in young women, recognized today as associated with defective diets, decreased gastric secretions, and chronic blood loss, would have been called chlorosis a generation ago." They exhibit symptoms of weakness. These patients will complain in the morning after a good night's sleep of not being refreshed by sleep, but in the afternoon and toward the evening, this weakened condition disappears. They are not necessarily pale. They complain of a tired feeling, headache, difficulty in breathing after bodily exercise, palpitation of the heart, pain in the side, and disturbances of menstruation. Dyspeptic symptoms are frequent.

¹Castle, William B., and Minot, George R.: *Pathological Physiology and Clinical Description of the Anemias*, New York, 1936, Oxford University Press.

They are often pale, but not necessarily so. The lips and visible mucosae are pale but the cheeks are not. The skin color may be pale yellow or pale green.

Clinical symptoms are as described above, plus dark spots floating before the eyes, disturbances in accommodation, and quick fatigue after reading. The retina is pale and is characterized by transparency of the blood vessels. There may be spasms with cold hands and feet. Thromboses have been described in this disease. The pulse is full, soft, and dicrotic. Blood pressure is normal. The spleen is not necessarily enlarged, according to Schilling, although von Noorden states that it is always enlarged.

One may distinguish between *puberty* chlorosis and *late* chlorosis. The first type is typical and classical; the latter type is not so typical.

Torpid chlorosis is a type of a chronic nature without any signs of regeneration in the blood.

Blood Picture in Chlorosis.—The blood picture is essentially a microcytic hypochromic anemia with a marked reduction of the hemoglobin. (See Plate XXIV.) In contrast to the hypochromic anemia of older women, gastric hyperacidity is common and achlorhydria is rare. Before a remission, the blood shows normal red blood cell content, the red cells are small and pale, and the color index is lowered. A moderate case shows hemoglobin values down to 50 or 60 per cent but the red cell count runs about normal, or about 4,000,000. This brings about a lowering of the color index. In severe chlorosis, the hemoglobin goes down to 20 per cent and the red cell count to 1,500,000 or 2,000,000. The color index and volume index are very low and the cells are very pale and small.

The most characteristic point about the blood picture of chlorosis is the presence of small and pale red cells (microcytes) and the constant lowering of the color index. With improvement, the color index is elevated.

Leukocytes in chlorosis show a normal or subnormal value, but at times there are leukocytoses up to 10,000 to 13,000. There is a lymphocytic decline in all these cases due to hypofunction of lymphatic apparatus. This lymphopenia is very characteristic.

There is a decline in the albumin content of the blood serum in all cases. They show a very pale watery serum. The diagnosis of chlorosis is largely based upon the anamnesis showing disturbances at the time of puberty in the female. There is a history of weakness and the other symptoms catalogued, which may spontaneously improve. Recurrences occur in the spring and fall, apparently without any known cause. Symptoms have already been described. These patients are usually frail, weak girls. Blood picture is an anemia of the secondary type with small pale red cells, lowered color index, and lowered red cell volume, no increase in the blood platelets; the serum is pale and hydremic.

In all probability, chlorosis was a form of hypochromic microcytic anemia. Moore² has written an interesting obituary to the so-called "idiopathic hypochromic anemias" which he believes likely are due to chronic blood loss. These cases remain idiopathic only because the site of blood loss often is not determined.

²Moore, C. V.: *Blood* 5: 876, 1950.

Severe iron deficiency anemia may occur in infants who are fed on an exclusive milk diet. We have observed such a child, aged 16 months, in whom the red count dropped to 1,600,000 and the hemoglobin was less than 5 gm. per cent. Treatment with iron cleared up the anemia.

Macrocytic Anemias

There are two factors which must be considered in the discussion of pernicious anemia and related macrocytic anemias, namely, the intrinsic and the extrinsic antianemia factors. The intrinsic factor is an indefinite something which is neither hydrochloric acid, rennin, pepsin, nor lipase. It is deficient in pernicious anemia. It is found in the gastric secretion in other types of anemia, including aplastic anemia and chronic hypochromic anemia. The extrinsic factor, which is measured by the production of a reticulocyte response in cases of pernicious anemia in relapse following its administration together with normal gastric secretion, is present in beef muscle and in many other foods. It is not ether soluble and it passes through an ultrafilter. It is known that the intrinsic factor is lacking in pernicious anemia. Macrocytic anemia occurs by reason of the lack of extrinsic factor in the diet or through a combination of dietary deficiency, insufficient intrinsic factor, or faulty absorption. Macrocytic anemia may also be caused by increased requirements, imperfect utilization, or faulty storage, or metabolism of an active hematopoietic principle in the liver.

Macrocytic anemias are classified as (1) tropical nutritional anemia, due to deficient diet; (2) following total gastrectomy, due to lack of intrinsic factor; (3) in sprue and pellagra, due to poor absorption as well as defective diet; (4) also found following resection of the intestine; and (5) in pernicious anemia of pregnancy. When macrocytic anemia is found in chronic and extensive liver disease, it is due to a faulty storage of liver principle and deranged function of the liver. The last word has not yet been written about the exact mechanism of macrocytic anemia.

Pernicious Anemia

Pernicious anemia is known also as Biermer's disease, or more properly, *morbus hunter-addisonii*. It is clinically a symptom complex of a severe megalocytic anemic type accompanied by marked intestinal symptoms, glossitis, achylia, dyspepsia and nervous symptoms, paresthesias, some cases showing the characteristic myelosis of Henneberg and various psychic changes in the individual.

This disease was formerly always considered fatal: once the diagnosis was made, the death warrant was practically signed; but with the discovery of liver therapy by Whipple, Minot, and Murphy and the therapy of hogs' stomach by Castle, this disease has largely lost its terrors; its victims have been practically recalled from death to life.

Etiology.—Pernicious anemia, as well as related macrocytic anemias, has been classified by Castle and Minot¹ as insufficient blood production due to nutritional deficiency of the bone marrow. Every type of macrocytic anemia

¹Castle, Wm. B., and Minot, George R.: *Pathological Physiology and Clinical Description of the Anemias*, New York, 1936, Oxford University Press.

showed prompt response to the administration of extracts of liver. If this liver therapy is discontinued, relapses occur. This seems to eliminate the former theories of infections, toxins, and noxae, to explain the etiology of anemia of the macrocytic type. It was discovered in 1926 by Minot and Murphy² that liver therapy was effective in the treatment of pernicious anemia. This seemed to emphasize the deficiency theory of pernicious anemia. Minot, Murphy, and Stetson³ proved that the reticulocyte response to the feeding of liver was a proof of the effectiveness of the agent. Castle⁴ and others showed that untreated patients with pernicious anemia were deficient in gastric secretion of an essential thermolabile constituent, or intrinsic factor. It was shown by Castle and Townsend⁵ that the gastric secretion of the normal individual was ineffective by itself. Similarly, beef muscle was also ineffective on administration to suitable patients with pernicious anemia. The beef muscle, called the extrinsic factor, when combined with the normal gastric secretion, increased blood production and clinical improvement similar to that induced by liver therapy.

Pernicious anemia, therefore, develops in individuals whose gastric juice contains insufficient amounts or none of the intrinsic factor to react effectively with the food. Expressed in other terms, normal gastric juice with food produces the active principle which is stored in the liver, kidney, and other tissues of normal individuals and permits normal bone marrow function to go on and thereby prevents anemia. Castle and his associates believe that pernicious anemia develops from a lack of the intrinsic or extrinsic factor or a little of each. They also believe that defects of intestinal absorption, even with a normal gastric mechanism, may lead to pernicious anemia. Sturgis and Isaacs⁶ showed that pig stomach was effective in the treatment of pernicious anemia and, therefore, this organ had the same substance present as normal gastric juice of man. The liver substance or factor that helps the bone marrow to return to normal in cases of pernicious anemia is able to resist boiling, while that in normal human gastric juice and in pig stomach is rapidly destroyed by temperatures above 70° C. Meulengracht⁷ proved that the factor is present in the pyloric region of the pig stomach.

The isolation of vitamin B₁₂ and related cobaltamines appears to have solved the problem of extrinsic factor, with which it has come to be identified. Jukes⁸ has summarized the biochemistry of folic acid and vitamin B₁₂. Vitamin B₁₂ has a molecular weight of 1550 to 1750 and contains cobalt which accounts for its red color. It is effective in microscopic quantities in producing a remission in patients with pernicious anemia when given parenterally. Oral administration is ineffective unless administered simultaneously with or shortly after ingestion of intrinsic factor. Rubbo⁹ presents the present-day concept of the enzyme systems involved in red blood cell production. He visualizes the action of folic (folinic) acid as catalyzing the pyrimidines from

²Minot, G. R., and Murphy, W. P.: *J. A. M. A.* **87**: 470, 1926.

⁸Jukes, T. H.: *Fed. Proc.* **12**: 633, 1953.

⁹Rubbo, S. D.: *M. J. Australia* **1**: 324, 1953.

methionine. The second stage involves vitamin B₁₂ as the catalyst for a combination of the pyrimidines and ribose (or desoxyribose) to form thymidine (nucleosides). Although a considerable amount of work has been done on vitamin B₁₂, showing its relation to nucleoprotein synthesis, there still remain many gaps in our knowledge of this complex mechanism. Assay of vitamin B₁₂ activity has been carried on by determination of growths of *Lactobacillus leishmanii*, *Escherichia coli* mutants, *Euglena gracilis*, and *Pateriochromonas stipitata*.

Glass and associates,¹⁰ using *Euglena gracilis* for assay, found oral administration of vitamin B₁₂ together with a potent intrinsic factor concentrate caused a sharp rise in vitamin B₁₂ blood level, but less than 0.5 per cent in the urine. A rise in urinary output of vitamin B₁₂ occurred after the reticulocyte peak.

Vitamin B₁₂ has been linked with various isotopes for experimental studies which have yielded a considerable store of information, most of which has been directed at determining mechanisms involved in the interaction of the various factors involved in macrocytic anemias. Tests based on the low urinary output of orally ingested radioactive vitamin B₁₂ have been used to detect pernicious anemia patients in remission.¹¹

The attack on the nature of intrinsic factor continues unabated and the elusiveness of this factor continues to interest and baffle investigators. Castle¹² has reviewed the development of knowledge concerning the gastric intrinsic factor and its relation to pernicious anemia. He concludes, after a scholarly exposition with extensive bibliography, that he is "sure that there is now general agreement at least on the present state of uncertainty about the nature and function of the intrinsic factor." He presents several theories, favoring the "catalyzed absorption theory" which assumes that intrinsic factor directly and specifically facilitates the absorption of vitamin B₁₂ by the intestinal wall. According to Castle, pernicious anemia "would not develop if the patient could effect daily the transfer of a millionth of a gram of vitamin B₁₂ the distance of a small fraction of a millimeter across the intestinal mucosa and into the blood stream. This he cannot do, principally as a result of failure of his stomach to secrete into its lumen some essential but unknown substance."

The symptoms of the disease are as follows: For a long period, patients show a gradually increasing fatigue with loss of appetite, vague symptoms of gastric disturbance, achylic in nature, with burning of the tongue or about the gums. These patients at this time display the so-called "Hunter tongue" or the "Moeller" glossitis, with rhagades about the mouth, gingivitis, marked dental caries, and extreme pallor. In these cases we note the light yellowing of the sclerae and other signs of possible hemolytic icterus. They show a golden yellow serum due to bilirubinemia as determined by the alcoholic (indirect) reaction of van den Bergh. We find here a dynamic icterus, urobilinuria and urobilinogenuria.

¹⁰Glass, G. B. J., Lillick, L. C., and Boyd, L. J.: *Blood* 9: 1127, 1954.

¹¹Schilling, R. F.: *J. Lab. & Clin. Med.* 42: 946, 1953.

¹²Castle, W. B.: *New England J. Med.* 249: 603, 1953.

There is usually complete achylia. The blood may or may not in the beginning show anemia, hyperchromia, and increase in size of red cells, while hemoglobin and total red cell values persistently remain normal. One must emphasize at this point that the most significant indication of pernicious anemia is the *increase in the size of the red cells*. The general impression of these patients is that there is something definitely wrong: unfortunately, unless they are thoroughly examined, they are likely to be labeled "neurasthenics," "gastric" or even "cardiac" and "liver" patients. The true diagnosis is suggested by the appearance of the tongue, the so-called Hunter tongue, or glossitis, which consists of little blistered elevations on the margins of the tongue, with some painful spotty areas together with flattening of the normal papillae. These patients now show achylic symptoms with a feeling

Fig. 192.—Pernicious anemia, blood film, showing hyperchromia, anisocytosis, poikilocytosis, macrocytosis, and a megaloblast. ($\times 950$.)

of fullness in the stomach or sudden diarrhea. They may develop nervous symptoms such as a numbness in the finger tips, which is due to disturbances in the terminals of sensory nerves. They also have disturbances in "taste," slight difficulty, too, with an otherwise good memory; they may show beginning impotency, perhaps slight unsteadiness in the gait; decreased or increased patellar reflexes, Babinski, paralytic or spastic ataxia.

Examination of these patients is suggestive of endocarditis, sepsis, carcinoma of the stomach, syphilis, cholangitis, chronic occult bleeding, or even a simple constitutional anemia.

There is another very remarkable phenomenon in pernicious anemia known as a "remission"—an unaccountable and sudden return to normal without any treatment. It is explained on the basis of an endocrine disturbance which at times, for some unknown reason, improves so that the patient returns to a normal status. The endocrine secretion, in other words, automatically works for the betterment of the patient and, at some time later, suddenly ceases to work, putting the patient once more into his former low status.

ADVANCED PERNICIOUS ANEMIA

BEFORE TREATMENT

1. Giant hypersegmented neutrophile
2. Monocyte
3. Lymphocyte
4. Cabot ring body and basophilic punctation in a macrocyte
5. Large blood platelet
6. Megalocyte
7. Poikilocyte
8. Polychromatic megalocyte
9. Polychromatic normocyte

Note anisocytosis, poikilocytosis, polychromasia, basophilic punctation. Erythrocytes are macrocytic hyperchromic.

AFTER LIVER THERAPY

PLATE XV.

The outcome of these cases is now favorable, but, as stated before, pernicious anemia was formerly considered a severe fatal anemia, preceded by a failing heart, edema of the lungs and subcutaneous tissues. Many of these cases developed the well-known funicular myelosis or Henneberg's myelosis; a severe spastic or tabes-like status, complicated with decubitus, bladder and intestinal paralyses. Many cases showed preagonally hemorrhagic diatheses, at times definite retinal hemorrhages. Occasionally, a patient dies with symptoms that are highly suggestive of aplastic anemia.

Blood Picture.—

The blood is watery, consequently spreads are very thin. The total white count is low, usually around 4,000 per cubic millimeter. The red cell count is low, 2,000,000 to 3,000,000 per cubic millimeter, sometimes as low as 320,000. Color index is high, owing to the disproportion between the count and the hemoglobin percentage. Color index may be 1.2, or 1.4, or even 2.0. In "remissions" the color index returns to 1.0. The blood serum has a golden yellow appearance so well described by Naegeli, with the alcoholic (indirect), van den Bergh test *positive* and the *watery* (direct) test *negative*. There is in this disease a megaloblastic blood picture with anisocytosis, poikilocytosis, and all degenerative forms of blood cells. The red cells, as stated above, are always definitely enlarged. There is no other form of anemia which shows such enlargement of red cells as we find in this disease. We find large hyperchromic cells, megalocytes, and occasionally a megaloblast. Particular attention must be called to the fact that a megaloblast as such shows a large circular nucleus with loosely woven chromatin and with a polychromatic or basophilic cytoplasm. Normoblasts may be large but they are not necessarily megaloblasts. Be careful to note the difference between a large normoblast and a megaloblast. It must be remembered, too, that *normoblasts* are often found in this disease but true *megaloblasts* are only occasionally found.

The white cells show a neutropenia and lymphocytosis with a characteristic disturbance or elevation of the monocytes; these monocytes show increased and abnormal nuclear margins. **The nuclei of the neutrophils are highly segmented.** There are sometimes 6 to 8 segments to the cell, united to each other by fine stringlike connections. Arneth called this his characteristic "right shift" or *hypersegmentation*.

Blood platelets are absolutely decreased and relatively increased and are irregular in form and size. The entire blood picture has been called the *Naegeli syndrome*.

"Blood crises" are present in the beginning of the remissions of pernicious anemia or shortly before death. Here we see many polychromatic and nucleated reds and also many regenerative leukocytes such as juveniles, myelocytes, promyelocytes, and even myeloblasts. The following hemogram is from a blood crisis during pernicious anemia.

Bas.	Eos.	Myel.	Juv.	Stab	Seg.	Lymph.	Mono.
-	-	-	2	15	68	7	8

For every 100 leukocytes there were 1,385 polychromatic normoblasts, 25 polychromatic macroblasts, 3 polychromatic megaloblasts, 2 cells in mitosis.

There were marked karyorrhexis; basophilic punctation, coarse; Howell-Jolly bodies; marked polychromasia; marked anisocytosis; and occasional myelocytes.

It is our custom to call a blood picture, in the absence of clinical symptoms, a *pernicious anemic blood picture* in reference to the above findings, but not necessarily a case of "*pernicious anemia*." It is interesting to note that from two to four days after the institution of liver therapy, there is a marked polychromasia and a marked increase in the reticulocytes. These can be well seen in the thick drop or with the supravital method. The red cells return slowly to their normal form and color. The existing hemolysis ceases. There is also a rise in the hemoglobin, together with a rise in the number of red cells, but the rise of the red cells is faster than the rise of the hemoglobin, thus making the color index fall below 1.0. Leukocytes take on the aspect of a hyperleukocytosis, often accompanied by an eosinophilia which has been described as an allergic reaction.

Diagnosis.—The Ehrlich-Naegeli syndrome, as above stated, must be found in order to think of this disease. The essential characteristic of the blood picture is a hyperchromia, marked anisocytosis, and megalocytosis. The increase in the size of the red cells is one of the most significant characteristics of pernicious anemia. There is a blood platelet change, leukopenia with lymphocytosis, a disturbance in monocytes, and a high segmentation of the neutrophils or a **right shift**. There are also oligocythemia, decreased hemoglobin and usually an elevated color index. By elimination, carcinoma, syphilis, *Diphyllobothrium latum* infestation, pregnancy, and sprue can be ruled out. One of the best methods for proving that a given case shows megalocytes, or increase in size of red cells, is to make a film from the suspected case and stain it in the ordinary manner with Giemsa. After it is dry, a very thin spread of normal blood is prepared *over this stained specimen*, allowed to dry, and then examined. The difference in size between the normal red cells and those of the given case can then be easily determined.

Hypersegmentation of the Neutrophils.—It has been known for a long time that there is a greater segmentation of the neutrophilic nucleus in pernicious anemia than in any other type of anemia. This was seen in the Arneth count when the number of cells with nuclei containing 3, 4, 5, or more segments is much higher than in normal blood. The increase in the cells of groups 4 and 5 of the Arneth count has been described by him as a "shift to the right" and is characteristic of the megaloblastic anemias. Some writers definitely state that this phenomenon is absolutely diagnostic of pernicious anemia, but it is difficult to agree with this statement in the light of the authoritative literature on the subject. In a monograph by Sturgis and Isaacs,¹ the following statement covers this question exceedingly well: "The polymorphonuclear neutrophils in pernicious anemia may have a greater percentage of nuclei with more lobes than normal; that is, the percentage of cells containing nuclei with 3, 4, 5, or more lobes is much greater in the blood of patients with pernicious anemia than in normal blood. This corresponds to what is described as a 'shift to the right' in the Arneth count, and it occurs frequently when the anemia is severe. While some regard this as diagnostic

¹Sturgis, Cyrus C., and Isaacs, Raphael: *Handbook of Hematology*, Vol. 3, p. 2251, Hal Downey, Editor, New York, 1938, Paul B. Hoeber, Inc.

of pernicious anemia, it is not characteristic of this condition alone as the same finding may be observed in other types of anemia. A 'shift to the left' takes place during the early stages of the remission."

Fleming² pointed out that the conditions in which a shift to the right occurs are pernicious anemia, sprue, and lymphocytic leukemia. Our own experience has noted its occurrence quite frequently in leukemia. Piney states that it occurs in certain cases of Hodgkin's disease prior to x-ray therapy. Davidson and Gulland³ state that the cell bodies of the polymorphonuclear leukocytes are oval and not round in this condition and that this applies both to the large forms and those of ordinary size; further, that this change is most commonly found in severe cases, and may affect all or nearly all the cells of that type to be seen in the blood film.

There are certain high lights in the diagnosis of this disease which must be emphasized: (1) Moderate anemia. (2) Changes in the blood platelets. (3) Erythrocytic changes, particularly increase in size. (4) Variations in size of the red cells. (5) Basophilic punctation, Cabot ring bodies, and polychromasia. (6) Occasional finding of megaloblasts. (7) Finding of normoblasts or nucleated red cells. (8) Neutropenia with high segmentation of the neutrophils, or Arneth's shift to the right. (9) Response of such cases to specific treatment. (10) Marked increase of reticulocytes first, after liver therapy, followed by a rise in the number of red cells before the hemoglobin begins to rise and consequent lowering of the color index is highly suggestive of the accuracy of the diagnosis of morbus addisonii. (11) Macrocytosis should attract one's attention to this disease even before an anemia is noted. (12) A high or even a normal white count almost rules out this disease in cases of suspected anemia. In all cases one finds a lowered white blood count, sometimes down to 4,000 per cubic millimeter. (13) It is claimed by Rous and Robertson⁴ that the small red cells or microcytes with pointed tails, which may be called poikilocytes, are indicative of an increased blood destruction. (14) Many basophilic punctated red cells are seen in this disease just as they are found in lead poisoning, but as a rule, *polychromatic young red cells* are not found in Addison's anemia except at the onset of improvement of a treated case. It is for this reason that the count of the reticulocytes is very important. (15) There are very low red blood counts in this disease, sometimes as low as 500,000. Carr⁵ reported 6 out of 148 cases with counts below 500,000. The lowest count in Carr's series was 320,000. Quinke reported a case with a count of 320,000. (16) The white count is very low due to the failure of the bone marrow to produce neutrophils. In other words, the lymphocytes are not interfered with, while the neutrophils are lowered. Consequently, there is a picture of relative lymphocytosis. The higher the lymphocytosis, the severer the prognosis, for the reason that the higher the lymphocytes, the more obvious it is that the bone marrow function for the manufacture of the neutrophils is partially destroyed. (17) As to the size

of the red cells, the majority exceed 8.5 microns in diameter. (18) The fragility test in this disease: the red cells in hypotonic salt solutions are normal, while in hemolytic jaundice their resistance is lowered.

Reticulocyte Response After Erythrocyte Maturation Factor Therapy.—

One of the most important phenomena in connection with the prognosis of this disease is the reticulocyte response after liver or other erythrocyte maturation factor therapy. In other words, after the use of these standard remedies, reticulocytes increase markedly in the peripheral blood. This is due to the increased maturation of the nucleated red blood cells in the bone marrow. This reticulocyte response does not show in the first five days of treatment for the reason that in this period the megaloblasts are developing into reticulocytes in the bone marrow. After the fifth day, there is a rapid increase in the number and percentage of reticulocytes. After the ninth to tenth day, there is a decrease in the percentage of reticulocytes accompanied by an increase in the total number of red blood cells. From time to time, thereafter, there are increases in the percentage of reticulocytes due to the stimulation of blood formation. The greater the dose of the remedial agent used, the more rapid will be the reticulocyte response. This is dependent, too, upon the route of administration, whether by mouth or by injection. The depth of the anemia in part determines the height of reticulocytosis; the more anemic the patient, the higher the reticulocyte response.

Folic Acid Therapy.—Some patients show a sensitivity to liver: inflammation around the needle point after injection, together with generalized itching sensitization of the skin. In such cases, recourse must be had to the use of folic acid (see pages 725, 1379, 1380). This is a vitamin which is known at this time to be very useful in the treatment of general macrocytic anemias, particularly the nutritional anemia in the southern part of the United States and the tropics. It is highly useful in sprue, in pernicious anemia of pregnancy, in anemias associated with chronic alcoholism, and in carcinoma of the stomach.

It has been well established that folic acid will cause a complete hematologic response and will maintain blood levels in patients with pernicious anemia. However, the neurological manifestations of this disease may continue to progress with folic acid therapy even though the hematologic response is satisfactory. For this reason, the use of folic acid *alone* is not recommended for the treatment of pernicious anemia.

Vitamin B₁₂ Therapy.—

In 1948 Smith¹ and Rickes and co-workers² isolated crystalline vitamin B₁₂ from liver. It was found that infinitesimally small amounts of this substance were effective in restoring normal hematologic values in pernicious anemia patients in relapse. The dosage schedule is a minimum of 1 µg per day, but larger dosages are generally used. Blackburn³ and Piney⁴ have re-

¹Smith, E. L.: *Nature* **161**: 638, 1948.

²Rickes, E. L., Brink, M. G., Koniuszy, F. R., Wood, T. R., and Folkers, K.: *Science* **107**: 396, 1948.

³Blackburn, E. K., *Med. Illus.* **7**: 511, 1953.

⁴Piney, A.: *Med. Illus.* **7**: 556, 1953.

viewed the modern treatment of pernicious anemia in excellent fashion. Our schedule has been 50 μ g intramuscularly daily for 7 to 10 days until a maximal reticulocyte response is obtained. Thereafter, 50 μ g dosage every second day is maintained until the erythrocyte and hemoglobin values are restored to almost normal values. Maintenance dosage of 20 to 30 μ g every two weeks appears quite adequate to maintain normal hematologic and neurological balance. Single doses greater than 50 μ g do not add to the effectiveness of treatment because amounts above a threshold value of 25 to 50 μ g by injection are rapidly and quantitatively excreted in the urine.⁵ Single massive doses at infrequent intervals cannot be substituted for regular injections at fairly frequent periods (two to three weeks) without the danger of relapse and the aggravation of central nervous system disease.⁵

A great deal of attention has recently been centered on the use of vitamin B₁₂ orally, especially when combined with mucosal extracts of hog stomach.⁶ Small doses of vitamin B₁₂ below 20 μ g are ineffectual when given alone, but when combined with intrinsic factor containing mucinous materials from hog stomach, responses are optimal or suboptimal. These observations are important in elaborating our basic understanding of the factors involved in pernicious anemia, but hematologists generally are opposed to oral preparations indiscriminately used. Suboptimal dosages may mask symptoms until irreversible neurological changes take place. The use of minimal dosages is decried because such dosages alter the bone marrow picture sufficiently to make diagnosis impossible and to date we have no clinical method of making an accurate diagnosis of pernicious anemia that supersedes the bone marrow picture in relapse.

Schilling⁷ has described a new test for intrinsic factor in which he has attempted to solve the dilemma of diagnosis in treated patients with pernicious anemia. The test consists of the administration of radioactive vitamin B₁₂ (B₁₂ Co⁶⁰) orally, followed in 2 hours by 1,000 μ g of nonradioactive B₁₂ parenterally. In normal subjects radioactive vitamin B₁₂ appears in the urine within 4 to 6 hours after the oral dose and this excretion continues for 24 hours. In pernicious anemia, no radioactive substance appears in the urine.

Another approach to diagnosis in the treated patient with pernicious anemia is the study of exfoliated material obtained by gastric lavage. Rubin and Massey⁸ have demonstrated a cell type in such washings which appears specific for pernicious anemia, and which was found in 20 of 21 patients who had been under therapy for years. These cells are markedly enlarged atypical columnar epithelial cells with nuclei approaching twice normal size.

Olmstead and Hirschboeck⁹ studied the fasting urorennin excretion in 50 patients with pernicious anemia and found that none of these patients excreted more than 0.5 rennin unit per 10 c.c. of urine. In a control group aged 40 to 90 years, 13 excreted less than 0.5 rennin unit, but the others excreted more than this. Their conclusions are that if the morning urorennin

⁹Olmstead E. G., and Hirschboeck, J. S.: *Am. J. M. Sc.* 226: 84, 1953.

excretion exceeds 0.5 rennin unit, it is likely that pernicious anemia is quite remote. On the other hand, excretions below 0.5 unit only imply the possibility of pernicious anemia but do not make a diagnosis.

The relationship of vitamin B₁₂ to the extrinsic and intrinsic factors of Castle continues to be of considerable interest; the subject has been exhaustively reviewed by Castle.¹⁰ He and his co-workers¹¹ believe that they have confirmed his theory that the primary function of intrinsic factor is to enhance the assimilation of vitamin B₁₂. Although many investigations are current, problems related to this phase of pernicious anemia are provocative.

Bone Marrow in Pernicious Anemia.—The principal change in the bone marrow in pernicious anemia is a replacement of the fatty marrow, normally found in certain bones, with a soft red marrow normally found in the sternum and ribs. There is an active increase of megaloblasts. Davidson and Gulland¹² found that the number of white cells in the bone marrow is greater than might be expected from the constant leukopenia present in the peripheral blood in these cases. Davidson and Gulland found also that the segmented neutrophils were reduced in number in the bone marrow and that the predominant type of leukocyte present was either the myelocyte or the lymphocyte. There is a marked decrease in the number of megakaryocytes. With improvement of the patient the large number of megaloblasts is changed into a condition where we see a greater number of normoblasts and erythrocytes. Doan and Zerfas¹³ found in supravital studies of the bone marrow in five cases of pernicious anemia 0.5 to 8.1 per cent polymorphonuclear neutrophils; 12.8 to 62.9 per cent neutrophilic myelocytes; 1.6 to 30.3 per cent eosinophilic myelocytes; 0.1 to 3.6 per cent basophilic myelocytes; 0.3 to 19.7 per cent myeloblasts; 0.0 to 0.8 per cent primitive cells; 3.4 to 6.7 per cent clasmocytes; 4.3 to 13.1 per cent monocytes; 0.0 to 0.6 per cent megakaryocytes; 5.8 to 20.1 per cent lymphocytes; no lymphoblasts; 0.0 to 1.5 per cent eosinophiles; 0.0 to 0.2 per cent basophiles; 0.6 to 14.4 per cent megaloblasts; 1.0 to 3.2 per cent normoblasts; 0.5 to 1.6 per cent unclassified.

The mechanism of the bone marrow changes is explained very well by the work of Minot and Murphy¹⁴ who showed that the red cells fail to mature because of the absence of a specific product of gastric digestion. When sufficient amount of this substance, which is supplied by erythrocyte maturation factor, is present in the blood, cells mature properly, and when this material is deficient, the development of the cells stops at the megaloblastic point, and a relapse occurs.

For further description of bone marrow in pernicious anemia, refer to page 932.

Sprue*

Sprue has been described as an insidious, chronic, remittent catarrhal inflammation of the alimentary canal occurring particularly in Europeans

*This article has been contributed through the courtesy of Dr. Ramón M. Suárez, of the Hospital Mimiya, Santurce, Puerto Rico. The tables and the microphotograph of the bone marrow were also furnished by Dr. Suárez. Dr. Suárez has had an unusual opportunity to study this disease in Puerto Rico.

who are residing or have resided in tropical or subtropical climates. Undoubted cases of sprue have been reported during recent years in people living in temperate climates, who had not visited the tropics. These cases appear in the literature as "nontropical sprue."

The disease is characterized by stomatitis and a bare, raw, painful tongue, recurrent attacks of cramps and diarrhea, voluminous, frothy, acid stools, loss of weight, and a severe anemia of the pernicious type.

The onset is usually insidious, and manifests itself first by soreness of the buccal mucosa, and vague digestive disturbances. The course is afebrile. The untreated patient gradually becomes weak, emaciated, irritable, and deadly pale.

The etiology is unknown. Only the concept of a deficiency disease has been able to withstand prolonged investigation. Castle, Rhoads, and their collaborators, while working in Puerto Rico, confirmed the belief that deficient diets frequently antedate the onset of clinical sprue. Surely the disease is not contagious. The theory of the "monilia psilosis" as a causative agent has been discarded.

Fig. 193.—Bone marrow showing megaloblasts, a large normoblast, and a neutrophilic juvenile cell. (Courtesy Dr. Ramón M. Suárez, Puerto Rico.)

The disease is endemic in the East Indies, and in South China, in India and Ceylon, in the West Indies and in Australia, in Japan, Korea, and the Philippine Islands. Its occasional occurrence in the United States is an accepted fact.

In a series of 150 cases studied in Puerto Rico, there were 121 whites, 26 mulattoes, and only 3 Negroes. The disease appears to be, therefore, extremely rare in the colored race. One-third of the patients were less than 40 years old, a point of difference from true Addisonian anemia.

In general appearance some of the older patients presented strong resemblance to persons with pernicious anemia. Loss of subcutaneous fat, and wrinkling and pigmentation of the skin, especially of the arms and legs, favor the diagnosis of sprue. In contrast to pernicious anemia the spleen was always normal or small. Although purpuric or scorbutic spots were occasionally found, retinal hemorrhages were uniformly absent.

The occurrence of osteoporosis and osteomalasia, reported as a common finding in nontropical sprue, was not found in the series of 150 cases already mentioned.

Investigations of the glucose tolerance showed uniformly a flat curve, favoring the theory of deficient intestinal absorption, and making the hypothesis of a possible pancreatic disease less important in the understanding of sprue. Moreover the pancreas has been found normal in a high percentage of cases studied at autopsy.

The anemia in sprue is macrocytic, usually hyperchromic, and rarely hypochromic. The mean cell volume averages 123.6 cubic microns, the color index 1.22. Nucleated red cells are very rarely found. Eosinophiles are reduced. The white cell count is below normal, averaging 5,280.

SPRUE 150 CASES	LOWEST	HIGHEST	AVERAGES
Hemoglobin	2.4 gm. (16.5%)	14.8 gm. (102%)	9.7 gm. (66%)

Mean Cell Hgb.	26 m. gm.	59 m. gm.	36.6 m. gm.
Mean Cell Hgb. (conc.)	20%	45%	26.1%

Studies of the aspirated sternal marrow yield interesting data. Megaloblasts are frequently seen. Usually there are more erythroblasts than normoblasts. Megakaryocytes, plasma cells, and monocytes were very rarely seen.

The second table shows the differential counts of the nucleated elements in the aspirated sternal marrow of sprue cases before treatment, and again 10 days and 2 months following the institution of parenteral liver therapy. The erythroblastic elements, originally 41.73 per cent, gradually diminished to 15.83 per cent; the myeloblastic cells increased from 53.5 per cent to 78.79 per cent; and the lymphoblastic elements in the marrow remained stationary during the observation period of 2 months.

The van den Bergh test is the same in sprue as it is in pernicious anemia; i.e., the test points to an increased degree of blood destruction. There is ap-

proximately normal or slightly increased resistance of red cells to hemolysis by hypotonic sodium chloride solution, which is just about what we find in pernicious anemia. A reduction in blood platelets may occur, but it is variable and not to be depended upon as a diagnostic measure.

The most striking pathologic finding at autopsy is the almost total disappearance of the subcutaneous fat. The intestines are markedly thinned out, this atrophy especially affecting the mucosa. All internal organs are smaller, especially the liver and heart. Histopathologic changes of a chronic or ulcerative colitis were found in 30 per cent of the cases.

Clinically, hematologically, and pathologically many of the cases of sprue are indistinguishable from Addisonian anemia. Low blood calcium figures have been reported in sprue, which is not the case in pernicious anemia. Achlorhydria, an almost constant finding in pernicious anemia, is found in only 30 per cent of sprue cases. Young children and adolescents are frequently affected with tropical sprue, and very rarely, if ever, with pernicious anemia. Cord changes or neurological manifestations, on the other hand, are extremely rare (about 2 per cent) in sprue.

The two most important factors in the treatment of sprue are an appropriate diet and adequate liver or folic acid therapy. Ashford* insisted on the necessity of a high protein, low fat and low carbohydrate diet. Liver extract should be administered parenterally. Both the diluted and the concentrated liver extracts have been found highly effective in all cases of sprue characterized by a macrocytic anemia, whether hyperchromic or hypochromic. Sprue is more resistant to treatment than pernicious anemia, and requires larger doses of liver. The use of folic acid in the treatment of sprue is discussed on pages 720, 1379, 1380.

Hemolytic Anemia

There are a number of blood dyscrasias which are grouped together as due to increased blood destruction. Paroxysmal hemoglobinuria, familial and acquired hemolytic jaundice, and sickle cell anemia are due to increased susceptibility of the red blood cells to destruction. There is a hemolysin present in the plasma in paroxysmal hemoglobinuria. In sickle cell anemia and hemolytic jaundice, where there is a physical peculiarity of the erythrocytes, precise knowledge of its relation to increased blood destruction is lacking, although recent advances in the knowledge of "molecular disease of hemoglobin" has given us a new lead as to the basic disturbances.

All cases of hemolytic anemia have in common the symptom of blood destruction.

Hemolytic anemias may be divided into acute, subacute, and chronic types. The acute cases are due to malaria and other protozoa; Bartonellae; bacterial toxins; chemical agents such as phenylhydrazine, saponin, trinitrotoluene, dinitrobenzol, aniline, amido and nitro compounds of phenol, benzol, toluol, lead, etc.; snake venoms; extensive burns; mismatched transfusions of isoagglutinogens A and B. All other types are those due to intragroup

hemolytic transfusion reactions and hemolytic disease of the newborn. The type described by Lederer below is an acute type. The causes of the chronic hemolytic anemias are classified as sickle cell anemia (see pages 734 ff.), chronic or acquired hemolytic jaundice, Cooley's anemia, and cases found with other chronic diseases, as pernicious anemia, Hodgkin's disease, and carcinomatosis.

In general, free hemoglobin and other blood pigments are found in the blood plasma, and hemoglobinuria is seen. The chief pigment found is methemoglobin, described by Fairley.¹ Hemoglobinemia, methemalbuminemia, and bilirubinemia are detectable in the plasma in all hemoglobinurias, depending on the rapidity and severity of the blood destruction. The bone marrow in acute hemolytic anemias is hyperplastic. Anemia due to the plasmodium of malaria is the result of destruction of red cells. This is a normocytic anemia. In blackwater fever due to *Plasmodium falciparum*, methemalbumin is found in the plasma as well as bilirubin. The cause of blackwater fever, as seen in severe malarial infections, is not definitely known. Various theories have been offered to explain it. Some believe it is due to sensitization to protein antigens of the malarial parasite produced by earlier infections. In Bartonella infections there is acute blood destruction. The most serious type of Bartonella infections found in the tropics is called Oroya fever due to the *Bartonella bacilliformis*. The vector is the Phlebotomus. Verruga peruana is due to the same organism.

Acute Hemolytic Anemia.—This is a type of anemia which occurs in the first two decades of life. Lederer² described three cases characterized by sudden onset, elevation of temperature, leukocytosis, and severe anemia, resembling pernicious anemia, all of which disappeared following a single blood transfusion. He maintained that these cases, of a type hitherto undescribed in literature, were due to an infection with selective action concentrated on the reticuloendothelial system. These cases showed a remarkable acuteness of the development of symptoms, evidences of very rapid erythrocytic destruction, extreme regenerative action of the bone marrow, rapid recovery after therapy, and the absence of sequelae. Clinically, cases began with headaches, weakness, yellowness of the skin, rapid pulse, and elevated temperature. One of Lederer's cases showed superficial retinal hemorrhages, localized mainly about the discs. All the evidences of a profound anemia with every manifestation of hyperfunction of the bone marrow were seen. A very close resemblance of the blood in pernicious anemia during a crisis was noted. Red cells with mitotic, pyknotic, fragmented, degenerated, and freshly extruded nuclei were found. Megaloblasts were easily demonstrated. A high degree of anisocytosis and poikilocytosis, numerous polychromatic cells, and cells with basophilic granulation dominated the picture. A pronounced macrocytosis and microcytosis were noted, and most of the cells appeared hyperchromic. Lymphocytes were but slightly increased in proportion to the myeloid cells. The latter showed in small quantities every type of cell associated with myelocytic leukemia, some undifferentiated, and others in various stages of dif-

¹Fairley, N. H.: Quart. J. Med. 10: 95, 1941.

²Lederer, Max: Am. J. M. Sc. 170: 500, 1925.

ferentiation. All these findings point to the stimulating action of some irritant, resulting in hyperfunction of hemopoiesis affecting the leukopoietic and erythropoietic elements equally.

Moschcowitz² noted a case which he called "an acute febrile pleiochromic anemia with hyaline thrombosis of the terminal arterioles and capillaries." He called it an undescribed disease although its essential characteristics definitely suggest its similarity to the case of acute hemolytic anemia described by Lederer. In his patient, a girl of 16, the onset was sudden with a rise in temperature, a few petechiae on the arm, and a red blood count of 1,330,000, hemoglobin of 40 per cent, leukocytes 12,600, of which 65 per cent were polymorphonuclears. A fragility test showed hemolysis complete at 0.19. Urine showed albumin and hyaline and granular casts. Patient showed partial paralysis of the left arm and leg and a slight facial paralysis. Patient died fourteen days after the onset of the disease. A partial necropsy was done. The heart muscle showed thrombi in the terminal arterioles or capillaries. Vessels were plugged with hyaline masses. These thrombi were first described by Klebs,³ who noted them in extensive burns. Schmorl⁴ found them in the stomach and liver after abrine poisoning. Flexner⁵ showed that they arose from agglutinated red cells, proving this by injecting the highly agglutinative substance, ricin, into rabbits.

Chronic Hemolytic Jaundice.—This is a pure type with an increased degree of susceptibility to hemolysis by hypotonic salt solution compared to the normal erythrocytes. Some authors consider the acquired type of hemolytic jaundice a manifestation of a latent familial case. The acquired types develop after attacks of malaria, syphilis, and other infections, but also occur without evident cause. In the familial type, the predisposition is transmitted as a Mendelian dominant by either parent. In some cases there are transient mild attacks with very little anemia; in other cases, there are persistent jaundice and severe anemia of a fatal type. As Castle and Minot⁶ state, "In the acquired type the patient commonly is 'more sick than jaundiced' and in the congenital often 'more jaundiced than sick.' "

There are also seen other atypical hemolytic anemias, sometimes described as atypical instances of hemolytic jaundice and at other times as an idiopathic hemolytic anemia. Refer to the section on Immunohematology for further discussion.

The blood picture in these cases showed reticulocytes, leukocytes and blood platelets increased when the patients are definitely jaundiced. The red cell count is low but may become normal in remissions. The reticulocytes are above 10 per cent. Baty⁷ described a case with 92 per cent reticulocytes. Red cells are small. There is increased susceptibility of the cells to hemolysis by hypotonic salt solution. Plasma pigments are increased and the indirect van den Bergh reaction is positive.

A case of idiopathic hemolytic anemia under observation in our service at the Christian Hospital, St. Louis, Mo., follows.⁸

The patient is a school girl, 9 years of age (1942). She had had a hemolytic anemia, unrelieved by splenectomy in 1934. Past diagnosis (before entrance into the Christian Hospital) was of Banti's syndrome.

Previous History.—The patient was admitted because of a severe rash, found to be scabies. Striking features of the case were the pasty, slightly cyanotic, and icteric color of the face. Enormous liver, extending 4½ inches below the costal margin in the nipple line; usual contour of the liver is preserved; there is no tenderness. Entire abdomen much distended, with flatness in both flanks. Kidneys are neither palpable nor elicited by percussion. Tonsils are in a poor condition. There are enlarged lymph glands in the neck region. Heart is enlarged to the left, the rate rapid and regular, with no murmurs.

Laboratory findings on admission were:

Fragility test: only very slight hemolysis beginning at 0.32%. Control hemolysis began at 0.40% and was complete at 0.34%.

Blood sedimentation: 6 mm. in 1 hour.

Stool: no blood, no leukocytes, no eggs or parasites.

Icterus index: 16.7.

van den Bergh: greatly delayed direct reaction, over 3 minutes; 1.4 units, indirect reaction.

Thrombocytes: absolute, 330,000 per cu. mm.; relative 106 per 1,000 erythrocytes.

Serology: negative.

X-ray: x-rays of the skull, ribs, spine, forearm, and both thighs reveal a marked increase in the total width of all bones. This is due to an increase in the medullary structures, with decrease in the size of the bone cortex. It is partially noted in the flat bones of the skull and pelvis. The spicule formation is typical of long-standing anemia, in which the bone marrow has assumed the production of excessive erythrocytes. *Conclusion:* Marked bone changes indicating erythroblastic anemia.

The blood picture and bone marrow counts on admission were as follows:

Blood:*

DATE	LEUKO-CYTES	ERYTHRO-CYTES	HGB. SAHLI	C.I.	B.	E.	M.	J.	ST.	SEG.	L.	MONO.	COAG. TIME	BLEED. TIME
4/17/40	27,150	3,280,000	40%	0.62	—	14	—	—	7	71	6	2	3'30"	2'45"
4/22/40	—	3,470,000	42%	0.61	—	3½	1	2½	9	41	38	4½	½ plasma cell (patient had been treated for scabies)	

For every 100 leukocytes, there were:

490 normoblasts

3 macroblasts

1 microblast

Many cells showed coarse basophilic punctation. There were large numbers of Howell-Jolly bodies, marked polychromasia, marked anisocytosis, with many hypochromic macrocytes, even hypochromic megalocytes, karyogenic metachromasia, karyorrhexis, marked hypochromia, many marginal granules, many poikilocytes. *Normocytic hypochromic erythrocytes with macrocytes.*

*See Plate XVI.

Bone Marrow:

Myeloblasts	3	For every 100 leukocytes, there were
Promyelocytes	10	2 erythrogenia
Eosinophilic myelocytes	1/2	15 p. megaloblasts
Eosinophilic "stabs"	1/2	23 p. macroblasts
Segmented eosinophiles	2 1/2	437 normoblasts
Basophiles	1/2	1 megaloblast with double nuclei, without signs of mitosis
Neutrophilic myelocytes	12 1/2	Coarse basophilic punctation, many Howell-Jolly bodies, marginal granules.
Neutrophilic juveniles	17	3 cells in mitosis
Neutrophilic "stabs"	19	
Segmented neutrophiles	25 1/2	
Lymphocytes	8 1/2	
Monocytes	1/2	
Plasma cells present		

A diagnosis of idiopathic hemolytic anemia was made. Patient now returns to the hospital every few months, remains about a week, and receives blood transfusions. Changes in the erythrocyte counts and hemoglobin percentages following the transfusions were:

Date	Erythrocytes	Hemoglobin, Sahli	Number of transfusions
7/29/40	1,950,000	28%	5—250 c.c. blood
8/ 3/40	3,000,000	52%	
10/14/40	2,480,000	38%	2—300 c.c. blood
11/17/40	3,150,000	51%	Leukocyte count: 21,400

The complete blood count, made before a series of transfusions, follows:

DATE	LEUKO- CYTES	ERYTHRO- CYTES	HGB.	C.I.	R.	E.	M.	J.	ST.	SEG.	L.	MONO.
7/13/41	18,750	3,040,000	48%	0.8	—	—	—	—	6	65	21	7

For every 100 leukocytes, there were:

- 1 polychromatic megaloblast
- 2 orthochromatic megaloblasts
- 1 polychromatic macroblast
- 203 polychromatic normoblasts
- 384 orthochromatic normoblasts, 63 with basophilic punctation, 1 with karyorrhexis
- 20 orthochromatic microblasts.

The total number of nucleated red cells was 611 per 100 leukocytes. Blood showed very marked anisocytosis and poikilocytosis; very marked hypochromia; marked basophilic punctation, both medium and coarse; slight polychromasia; many macrocytes; occasional orthochromatic and polychromatic megalocytes, all hypochromic; very many Howell-Jolly bodies; slight karyogenic metachromasia.

Blood count made in May, 1942:

LEUKO- CYTES	ERYTHRO- CYTES	HGB.	C.I.	R.	E.	M.	J.	ST.	SEG.	L.	MONO.
28,500	2,230,000	44% (S)	1.0	—	3	2	10	11	43	23	8

For every 100 leukocytes, there were:

- 91 polychromatic normoblasts
- 11 orthochromatic normoblasts
- 2 orthochromatic normoblasts in karyorrhexis
- 7 polychromatic microblasts
- 28 polychromatic macroblasts
- 18 polychromatic megaloblasts
- 147 nucleated reds, total

There was moderate anisocytosis and poikilocytosis, slight polychromasia, slight basophilic punctation (fine), many fragmentary nuclear structures, Cabot ring bodies, and Howell-Jolly bodies.

Thalassemia

Thalassemia is a hemolytic anemia associated with an inherited intracorpuseular defect of erythrocytes. First differentiated by Cooley and Lee,¹ it has often been referred to as "Cooley's anemia." This syndrome has also been designated "Mediterranean anemia" or "Mediterranean disease." The latter designation has been applied chiefly because the syndrome has occurred most frequently in people of Mediterranean stock, with Italians predominating. Although scattered cases had been described in non-Mediterranean stock, it was not until Minnich and her co-workers² reported 32 cases in Thailand that any considerable number had been collected outside of this group. In subsequent studies, most of these cases were found to be a combination of Mediterranean-E hemoglobin disease rather than pure thalassemia.³ It is quite generally agreed today that the syndrome is due to an inherited characteristic of the erythrocyte⁴ as a recessive gene. Two major subdivisions are recognized: (a) the symptomatic disease form, thalassemia major, and (b) an asymptomatic form, thalassemia minor. Thalassemia major is the homozygous disease form with a double dose of the gene for the syndrome, whereas thalassemia minor is the heterozygous trait form, having only one of the genes for Mediterranean disease. In addition to these major divisions, studies of electrophoresis and alkali denaturation have revealed combinations of thalassemia and molecular disease of hemoglobin. Examples of such combinations are sickle-thalassemia disease, thalassemia-C disease, and thalassemia-E disease (see section on molecular disease of hemoglobin, pages 734 ff.). The combination of sickle-thalassemia is sometimes referred to as "microdepranocytosis."

In the disease form, anemia is a striking feature, varying in intensity from case to case, but often of sufficient severity to cause symptoms. An outstanding feature of the disease is the x-ray appearance of the skull which shows perpendicular striations suggesting hair standing on end. Involvement of other bony structures may be present, and in the hands it takes on a mosaic pattern. Splenomegaly may occur and at times reaches fairly high proportions. The hemolytic crises are often attended by febrile periods but jaundice is infrequent. As a result of the anemia, debility, and perhaps a lessened resistance, intercurrent infections are fairly frequent and life expectancy is considerably reduced, so that many of these patients do not live beyond childhood.

The blood picture in the disease form shows an anemia of variable degree, ranging from 1,000,000 up to 3,500,000 red cells per cu. mm. There is a pronounced lowering of the hemoglobin and hematocrit values, with a resultant hypochromic microcytic anemia. The blood spread not only reflects this hypochromasia and microcytosis but also shows marked poikilocytosis and anisocytosis. During and shortly following a hemolytic crisis, nucleated erythrocytes

⁴Valentine, W. N., and Neel, J. V.: *Am. J. M. Sc.* 215: 456, 1948.

are commonly seen in the blood spreads and Howell-Jolly bodies may be present. Target cells in varying numbers are so regularly encountered that their presence in a blood spread should always suggest thalassemia as a possible diagnosis. Reticulocytes are often increased. There are no significant changes in the platelets. The leukocyte count may be considerably elevated during a period of hemolytic crisis. The bone marrow is usually hyperplastic, displaying a normoblastic hyperplasia, which is not a specific characteristic enabling a diagnosis of the disease.

Fragility studies of the erythrocytes show either a normal osmotic fragility or may show an increased resistance in hypotonic saline. Red cell survival studies reveal a diminished survival time in some cases and a normal survival in others.⁵ The observations of Singer and associates⁶ that thalassemia major displays a considerable increase in hemoglobin F have been verified by many observers.

In thalassemia minor, there are no symptoms referable to the disorder. Although anemia is not present, target cells may be found in the blood spreads in lesser numbers than in the disease form. The same is true of the amount of fetal (F) hemoglobin.

In the combinations of thalassemia and sickle cell hemoglobin C or hemoglobin E, the clinical and blood pictures appear to have a position intermediate between thalassemia disease and thalassemia trait. Although sickling is not present in thalassemia alone, when it combines with the sickle form, sickling of the red cells is demonstrable. Electrophoretic studies in these combinations demonstrate the abnormal hemoglobin S, C, or E, as well as F. However, attention is again called to the fact that hemoglobin F has a mobility approximating that of A and cannot be readily demonstrated by paper electrophoresis.

Paroxysmal Nocturnal Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria, often referred to as the Marchiafava-Micheli syndrome, is associated with a chronic hemolytic anemia with acute paroxysms of hemolytic crises occurring at night. These crises are of sufficient degree to result in hemoglobinuria. Although the red cell is the predominant hemopoietic element involved, the white cells and platelets may also be affected. Crosby⁷ has presented a magnificent review of this syndrome, together with many of his original observations. He concludes that paroxysmal nocturnal hemoglobinuria is an acquired disease of the hemopoietic system in which abnormal red cells, white cells, and platelets are then susceptible to some normal plasma factor, which is believed to be properdin.⁸ This serum euglobulin is distinct from complement and the components of the clotting system but requires complement and magnesium ion for its activity. Crosby calls attention to the fact that hemolytic crises occur when the patient is asleep (whether at night or day), and that during this period changes in the balance of an inhibitor-hemolysin system may account for the crises. Others

have felt that changes of pH are produced by retention of CO₂ during sleep; this observation forms the basis of the Ham¹ acidification test and its modifications.

In addition to the anemia, these patients develop leukopenia, which may become chronic, and perhaps contributes to the increased susceptibility to infection that these patients show.

Thrombocytopenia is generally not marked and purpura is uncommon. However, agglutination of platelets in this disease accounts for the vascular thromboses seen in paroxysmal nocturnal hemoglobinuria. There appears to be some evidence of a vicious cycle of competition between members of the coagulation mechanism (especially thrombin) and the factors involved in paroxysmal nocturnal hemoglobinuria. Dicumarol has had some beneficial effect in protecting these patients against thrombotic episodes and perhaps the development of anemia. Heparin, on the other hand, causes increased hemolysis.

Paroxysmal Cold Hemoglobinuria

This condition is found in syphilis and is often acutely brought on by sudden chilling of the body surface. The urine is diagnostic; if taken directly after or during the attack, color varies from brown red to black; acid reaction; specific gravity very low; on boiling, a brown coagulum of albumin develops; hyaline casts are present; spectroscopically, bands of hemoglobin and methemoglobin; there are no red cells in the urine; urine contains urobilin.

During the attack we may find the following *Donath-Landsteiner auto-hemolysis phenomenon*: Place some blood in a test tube. Chill to 5° C. for ten minutes. Warm to 37° C. Hemolysis will occur. Normal blood will show no such hemolysis. This test is based upon the fact that in this disease a special hemolytic substance has been liberated into the blood stream. We note, too, in the blood picture, leukopenia, hypochromia, and poikilocytosis during the attack.

Blood Picture in Bartonellosis

The blood picture in bartonellosis, according to Groot,² shows a rapid, progressive anemia. Erythrocyte counts of 1,000,000 per cu. mm. are common. The rate of decrease is rapid, with as many as 300,000 red cells per cu. mm. lost in 24 hours.

The volume, diameter, and thickness of the erythrocytes is greater than normal. The mean hemoglobin concentration is usually low, but may be normal. Hyperbilirubinemia is often observed, but is not constant. The bone marrow is regenerative, with large numbers of reticulocytes and normoblasts in the peripheral blood, the number of such elements being proportional to the seriousness of the anemia. Megaloblasts are often found.

Bartonellae are found in the red blood cells, the number varying. At times, 99 per cent of the red blood cells are infected, and often it is possible to find 10 to 15 organisms in a single cell, although these are extreme cases. Basophilic erythrocytes and macrocytes are usually less infected. Reticulo-

¹Ham, T. H.: A Syllabus of Laboratory Examinations in Clinical Diagnosis, Cambridge, Mass., 1950, Harvard University Press, p. 167.

²Groot in Clinical Tropical Medicine, by Gradwohl, Benitez Soto, and Felsenfeld; St. Louis, 1948, The C. V. Mosby Co.

cytes seldom are infected unless the number of Bartonellae in the blood is very high. Normoblasts are seldom infected except in rare cases. Bartonellae are sometimes seen in the cytoplasm of monocytes.

At the beginning of the disease, there is leukopenia, although the number of white blood cells is normal in uncomplicated cases.

There is no typical differential count. At times either a very slight lymphocytosis is noted or, more commonly, polymorphonucleosis.

During the period of anemia, there is an increase in young polymorphonuclears, etc., in the myeloid series.

The sedimentation rate is greatly increased, 100 to 172 mm. in one hour being noted in the Westergren test.

Autoagglutination phenomena are rare.

According to Schilling, this is the only acute infection which causes a severe anemia of the megalocytic type.

Molecular Disease of Hemoglobin

Pauling's¹ discovery of the differences in electrophoretic mobility of normal and sickle cell hemoglobin has opened a rapidly growing field in the investigation of hemoglobin. The basic concept of this work is that hemoglobin exists in various molecular structures that differ from that of normal hemoglobin. These differences can be elucidated by electrophoresis, as well as by other methods such as gel formation,² tactoid formation in phase microscopy,^{2, 3, 7} and alkali denaturation.⁴ The technic of paper electrophoresis for studying proteins, including hemoglobin,^{5a, 5b} has supplemented the much more complicated and expensive Tiselius apparatus, and has opened the way to large-scale investigation of diseases associated with hemoglobin molecular disease.

The **nomenclature⁶ of the various types of hemoglobin** now described on the basis of electrophoretic patterns are as follows:

(a) Normal adult hemoglobin, or hemoglobin *A*; (b) normal fetal hemoglobin, or hemoglobin *F*⁴; (c) sickle cell hemoglobin, or hemoglobin *S*⁹; (d) hemoglobin *C*^{9, 10, 11}; (e) hemoglobin *D*^{8, 9}; (f) hemoglobin *E*¹² and an unnamed hemoglobin¹³ which appears to have a position intermediate between *F* and *S*.

These hemoglobin types are inherited. Neel¹⁴ has reported the inheritance pattern of the sickling phenomenon in 75 kindreds. He maintains that this phenomenon is "due to a gene which in single dose (heterozygous condition) produces only the sickle cell trait, and in double dose (homozygous condition)

sickle cell disease." Translated into terms of abnormal hemoglobins, patients with sickle cell trait are represented by an S-A gene pattern, whereas those with sickle cell disease have an S-S pattern. The same principle applies to other combinations of abnormal hemoglobins. In the trait, quantitative

Fig. 194.—Electrophoretic determination of hemoglobin types. Separation of hemoglobins by filter paper electrophoresis. (Weinstein, I. M., Spurling, C. L., Klein, H., and Neeheles, T. F.: *Blood* 9:1157, 1954. By permission of the authors and publisher.)

electrophoretic studies show small amounts of abnormal hemoglobin in combination with relatively large amounts of normal hemoglobin. On the other hand, the disease syndrome reveals almost 100 per cent abnormal hemoglobin. Motulsky and his co-workers¹⁵ report the following typical distribution of

TABLE 53.—DISTRIBUTION OF VARIOUS TYPES OF HEMOGLOBIN

	HEMOGLOBIN TYPE					
	A	S	C	D	E	F

hemoglobins in various syndromes observed by them or collected from the literature. Table 53 is a modification, based on observations made subsequent to their report.

The electrophoretic mobilities of the various hemoglobins follow the order of $A > F > E > S(D) > C$. The mobility of hemoglobin F so closely approaches the speed of hemoglobin A that these two components are generally inseparable in the paper electrophoresis technic, although Smith and Conley¹⁶ claim such separation is possible. In the Tiselius apparatus, the F component can be readily identified. In most clinical studies, the alkali denaturation technic⁴ has been the method of choice for demonstrating F-hemoglobin. D-hemoglobin has the same mobility as S-hemoglobin and cannot be separated by electrophoresis. Differences in solubility⁹ have been used as a means of distinguishing these two components.

The presence of these various abnormal hemoglobins may or may not result in symptoms. In general, patients with a homozygous pattern and high percentages of abnormal hemoglobin show marked symptoms. Hemolytic crises with resultant anemia are prominent features. Associated with these crises are severe abdominal pain, fever, headache, hematuria, pallor, tachycardia, and dyspnea. Abdominal pain may be so severe as to suggest a surgical condition of the abdomen, and patients in this category have been mistakenly operated upon as emergencies. Jaundice, as a result of excessive red blood cell destruction, is quite common, and hematuria is found occasionally. Vascular thromboses may result in a multiplicity of symptoms with the brain a fairly common site for such episodes. On physical examination, the degree of pallor is proportionate to the anemia. Jaundice may be present. Splenomegaly and sometimes hepatomegaly are quite common. In the heterozygous state, abnormal clinical findings are absent and the patient's history is essentially negative. In combined states, such as sickle-C hemoglobin disease, the clinical picture is generally intermediate in severity between the homozygous and heterozygous conditions. Although the picture is generally milder in such combinations, Smith and Conley¹⁶ call attention to two patients in whom hemolytic crises were sufficiently severe to produce jaundice and profound anemia.

Just as the clinical pattern seems to follow the types of hemoglobin present, there also appears to be some parallelism in the hematologic studies. In the *homozygous* states, generally, an anemia of varying degree occurs and may be quite profound. The stained blood spreads show numerous target cells, ranging from 60 to almost 100 per cent of the red blood cells. During crises, anisocytosis (chiefly microcytosis) and poikilocytosis are marked, and nucleated erythrocytes are common. Polychromasia is often seen. In those patients with sickle cell disease, sickled erythrocytes may rarely be seen on the blood spread. Osmotic fragility studies reveal an increased resistance. Mechanical fragility tends to be normal in an oxygen atmosphere but is increased in an atmosphere saturated with carbon dioxide. Reticulocytes are often increased, especially during or shortly after a hemolytic crisis. Siderocytes, which are iron-staining bodies within the erythrocytes, tend to be numerous.¹⁷ Sickling is dem-

¹⁶Smith, F. W., and Conley, C. L.: Bull. Johns Hopkins Hosp. 93: 94, 1953.

¹⁷Kaplan, E., Zuelzer, W. W., and Neel, J. V.: Blood 8: 735, 1953.

onstrated only in patients with hemoglobin S and may approximate 100 per cent in some instances. In this respect, it is important to point out that sickling of such proportion occurs only in the homozygous S state. Homozygous C and E and thalassemia are not accompanied by sickling phenomenon. When these are combined with sickling such as sickle-C hemoglobin disease, sickling will occur but to a lesser degree than in homozygous S.

Combinations of sickle cell and other abnormal hemoglobins, such as sickle-C hemoglobin disease, show intermediate hematologic values. Kaplan, Zuelzer, and Neel¹⁷ were particularly impressed with the markedly high target cell incidence in sickle-C hemoglobin disease. Apparently variations in hematologic abnormalities may show the same wide variations that the clinical pictures display, ranging from relatively mild to very severe.

In the *heterozygous* or *trait* states, hematologic studies reveal minimal deviations from normal. Anemia is not present. Target cells occur much more frequently than in normal people but the percentage of such cells rarely exceeds 20 per cent. Osmotic fragility tends to be normal or occasionally decreased, and mechanical fragility is generally normal or only slightly affected in CO₂. Siderocytes are absent or rare. Sickling in wet preparations is minimal, rarely exceeding 20 per cent in subjects with S-hemoglobin.

From a clinical standpoint, the relationship of F-hemoglobin concentration to disease is not quite as clear-cut as with the other abnormal hemoglobins. Its high concentration in newborn infants (almost 100 per cent) is not implicated in any disease process. Singer and his co-workers⁴ originally demonstrated its association with sickle cell disease where values ranging from 2.0 to 23.9 per cent were found. Since this original publication, denaturation studies have taken on a pattern. Sickle-C disease and sickle-thalassemia disease are both associated with high values for fetal hemoglobin. Thalassemia major is also associated with increased F-hemoglobin values. Mild elevation of F-hemoglobin has been noted in E disease. When thalassemia is combined with other abnormal hemoglobins (e.g., thalassemia-E disease), fetal hemoglobin values are elevated. In the trait states of S-hemoglobin or thalassemia minor, the values are normal. Increased amounts of F-hemoglobin have been noted in some miscellaneous conditions, such as hereditary spherocytosis, chronic aregenerative anemia, untreated pernicious anemia, myelophthisic anemia, and some leukemias.

Sickle Cell Anemia

This form of anemia was first seen by Herrick¹ who observed peculiar elongated and sickle-shaped red blood corpuscles in a case of severe anemia. He did not recognize this as a distinct clinical entity, but it is now recognized as such. The disease is a familial one occurring mainly in Negroes or mulattoes. It was generally believed that it was an intrinsic characteristic of the Negro, until Cooley and Lee² reported a case in a four-year-old American-born Greek boy. Since then, other cases have been reported in Italians, Sicilians, and even in a boy of Scottish-Irish parentage. It has been found as a latent

¹Herrick, J. B.: Arch. Int. Med. 6: 517, 1910.

²Cooley, T. B., and Lee, P.: Am. J. Dis. Child. 32: 334, 1926.

phenomenon in 6 or 7 per cent of several series of supposedly normal Negroes. These cases show clinically a greenish yellow scleral discoloration. L. W. Diggs, of the University of Tennessee, has made a special study of this type of anemia. He states that the average age of death of these patients is eleven years, showing its high incidence in the young.

In West Africa, the ancestral home of most Negroes, sickle cell anemia received attention of Russell and Taylor in 1932, Smith in 1934, Reid in 1936, and Evans in 1944 and 1945. Findlay, Robertson, and Zacharias¹ reported on the incidence of sickle cell anemia in the British West African colonies. The technic was simple owing to field conditions. After cleaning the skin, a drop of blood was placed on a glass slide, covered with a clean cover glass, and ringed with petrolatum. Ringed preparations, protected from ants, were kept at room temperature and examined after 24 hours. In all, 5,500 Africans were examined, of whom 12.4 per cent showed the sickling trait. One-half of the number were natives of the Gold Coast and French Togoland, the remainder came from Gambia, Sierra Leone, and Nigeria. Sickling was found in all tribes and no significant specific tribal differences were noted; 11.2 per cent were males and 12.6 were females. They suggested that the expectation of life in those with sickling of the cells may be less than in normal persons. They investigated the incidence of sickle cell anemia in relation to certain physiologic and pathologic conditions, for instance, in pregnancy. Of 455 pregnant women examined, 77, or 16.9 per cent, showed sickling.

Fig. 195.—Sickle cell anemia, stained film. ($\times 950$.)

Sterility.—Of 61 women who either had never conceived or had failed to produce a live fetus, thirteen, or 21.3 per cent, showed the sickling trait.

Lunacy.—The rate of 6.5 per cent is comparable to that in old people without mental disease.

General Morbidity.—Fifteen and eight-tenths per cent (15.8) showed sickling.

Pneumonia.—It was attempted to determine whether or not jaundice seen in Negroes with pneumonia can be correlated with sickle cell anemia. Five and two-

¹Findlay, G. M., Robertson, W. M., and Zacharias, F. J.: *Tr. Roy. Soc. Trop. Med. & Hyg.* 40: 83-86, Aug., 1946.

tenths per cent (5.2) of West African soldiers who had pneumonia had jaundice. Of these pneumonia patients, 1,240 in all, 125 had sickle-shaped cells, and of the 125 with sickling, twelve, or 9.4 per cent, had jaundice. Difference in the incidence of jaundice in those with sickling and those without sickling is not particularly significant. In this communication, sickling in races other than Negroes was looked for with the following result—568 British soldiers were all negative and 188 Syrians were also all negative.

Blood Picture.—

The blood picture in sickle cell anemia shows sickle-shaped erythrocytes, often not typical in stained spreads, but 75 to 100 per cent are distorted in moist preparations. This sickling has often been observed in isotonic salt solution. Sydenstricker* concluded that the presence of serum is essential for this change in the cells. There is present a normocytic normochromic anemia. Signs of regeneration in the blood are seen in an increase in reticulocytes, diffuse basophilia, the presence of nuclear particles, nucleated red cells, and megalo-blasts. We have here anisocytosis, anisochromia, and poikilocytosis.

The differential blood count is variable, usually with a left shift of the leukocytes. There is also an increase in blood platelets. Bleeding and coagulation times are normal. There is a decrease in fragility, but normal sedimentation.

Demonstration of Sickling of Erythrocytes

Method I, In Vivo Anoxia, Scriver and Waugh¹

Place a rubber band around the finger for 5 minutes.

Obtain a drop of blood from the finger and quickly place it under a coverslip.

Seal the edges of the cover slip with petrolatum.

Observe for sickling for several hours.

Method II, Metabisulphite Method of Daland and Castle²

Add 1 drop of blood

to 2 drops of a freshly prepared 2% aqueous solution of sodium metabisulphite on a glass slide.

Cover with a cover slip and observe in 15 to 30 minutes.

With this method, sickling occurs promptly. In sickle cell *disease*, 60 to 80% of the red cells may show sickling, whereas in sickle cell *trait* only a small percentage (5%) may show sickling.

Bone Marrow Findings.—

Bone marrow studies in sickle cell anemia have not been touched upon with much frequency. Sydenstricker³ found the bone marrow to be abundant, bright red in color, and thin in consistency. Huck⁴ and Sharp and Schleicher⁵ confirmed these observations. In addition, the latter compared various quali-

tative and quantitative studies on bone marrow and peripheral blood of an adult Negro with similar observations made on an adult Negress. Their differential counts are shown in Table 54.

TABLE 54.—DIFFERENTIAL CELL COUNTS ON BONE MARROW OF TWO CASES OF SICKLE CELL ANEMIA

CELLULAR ELEMENTS	PATIENT 2	PATIENT 3
	♀	♂
<i>Leukocytes</i>	<i>per cent</i>	<i>per cent</i>
Leukoblasts	3	3
Premyelocytes	7	10
Myelocytes, eosinophilic	3	4
Myelocytes, basophilic	1	1
Myelocytes, neutrophilic	13	18
Metamyelocytes, neutrophilic	17	23
Neutrophile, stab	20	18
Neutrophile, segmented	25	15
Eosinophiles	5	2
Basophiles	1	1
Lymphocytes	3	4
Monocytes	2	1
<i>Erythrocytes</i>		
Reticulocytes	15.8*	21.2*
Megalóblasts	12.0	3.2
Normoblasts	40.0	12.8
Mean diameter	7.8 μ	7.8 μ

*Reticulocytes given in per cent of erythrocytes and were counted separately after supravital staining.

The peripheral blood patterns of these two patients during their anemia phase were also compared with that of an adolescent Negress with sickle cell anemia. Their hematologic observations on their second patient are found in Table 55.

TABLE 55.—PATIENT 2. PERIPHERAL BLOOD
(Negress, 26 years of age, third trimester of pregnancy)

Erythrocytes	940,000 per cu. mm.
Mean diameter	8.1 microns
Thrombocytes	110,000 per cu. mm.
Reticulocytes	20.2%
Hemoglobin	25.0% (Newcomer)
Bleeding time	4.5 minutes
Coagulation time	3.0 minutes
Fragility	0.38 to 0.28% sodium chloride
Leukocytes	11,460 per cu. mm.
Myelocytes	1%
Metamyelocytes, neutrophilic	2%
Neutrophiles, stab	26%
Neutrophiles, segmented	49%
Eosinophiles	1%
Basophiles	1%
Lymphocytes	18%
Monocytes	2%

Among 100 leukocytes were found 28 per cent megaloblasts, 44 per cent normoblasts, and 12 per cent microblasts. The reticulocytes were predominantly young types showing heavy wreath forms of reticulation. There were marked anisocytosis, poikilocytosis, and polychromasia. Many stippled erythrocytes were found along with a small number of ovalocytes. The

thrombocytes varied in size and appeared toxic. The neutrophilic series showed a severe left shift of a degenerative type. There were many toxic granules.

In experimental work they showed that the sickling trait of the erythrocytes can be overcome by washing in saline and reinduced by addition of the patient's blood serum.

Sickling occurs in bone marrow cells of sickle cell anemia when sealed in normal serum from an individual of the same blood type. Blood cells from a normal individual of the same blood type retain their normal contour when in contact with serum from a case of a sickle cell anemia for a period of six days. The offspring of a patient showing severe sickle cell anemia did not manifest the sickling trait immediately after birth.

Pathology.—Sickled red blood cells; congested capillaries. There are a thrombocytic tendency, infarcts, fibrosis, anemia; and degenerative visceral changes are noted in the organs. There is hemolytic jaundice with pigmentation. The marrow is hyperplastic with evidence of accelerated hematopoiesis of all elements within the bone marrow. Unusual forms of red cells are found in specimens of bone marrow which have been prepared in Formalin. The lymph glands show marked hyperplasia. A number of observers have noted phagocytosis of red cells by reticuloendothelial cells in liver, spleen, and lymph glands. There are congestive splenic enlargement and early hemorrhage. There are siderotic nodules in the spleen. Fibrotic atrophy occurs late, as has been described by Diggs. There are hepatomegaly and some evidences of kidney degeneration. Leg ulcers are commonly seen.

Among other *laboratory findings*, there are the following: Hyperbilirubinemia; negative direct van den Bergh test; urobilinuria; albuminuria and casts; gastric hyperacidity; dark stools; roentgen ray changes in bones.

According to Diggs, the sickle cell trait is noted as follows: Best demonstrated by moist preparations; dominant Mendelian characteristic: 8 per cent incidence in Negroes; incidence in whites—rare authentic cases confined to the Mediterranean area.

The pathologic physiology of sickling was undetermined until Pauling demonstrated that the hemoglobin of sickle cell anemia (S-hemoglobin) had an electrophoretic mobility different than that of normal hemoglobin. He postulated this condition as a "molecular disease of hemoglobin." Many studies have verified and amplified these observations and they are covered in this edition under the section, "Molecular Disease of Hemoglobin," pages 734 ff.

Eadie and Brown¹ have critically reviewed the literature on red cell survival studies. In sickle cell anemia, it is known that when blood from a patient with the disease is transfused into a normal recipient, cells disappear rapidly at first and then more slowly with some cells living out a normal life span. The shortened survival time has been generally considered a function of the amount of abnormal hemoglobin in individual cells, those having the highest percentage of hemoglobin S having the shortest survival time. These

¹Eadie, G. S., and Brown, I. W., Jr.: *Blood* 8: 1110, 1953.

observers take exception to this view and suggest that random mechanical destruction plus normal senescence account for the disappearance rate in sickle cell disease.

Neel² has frequently been associated with discussions relating to the inheritance of sickle cell disease as a Mendelian dominant. He postulates a homozygous combination of genes as responsible for sickle cell anemia and a heterozygous combination as the picture in trait. In families in which sickle cell disease is found, both parents have the trait and 1 out of 4 children on the average inherits the pathologic gene from both parents to develop the disease. To date this is the group most frequently studied. As the new forms of molecular diseases of hemoglobin are uncovered, the problem becomes more complex. Combinations of sickle cell with hemoglobin C have been described and other combinations will undoubtedly be forthcoming. This second type has a lower frequency than sickle cell disease, and Neel indicates that in 6 per cent of Negro families in which sickle cell disease was present, the disease was due to a combination of sickle cell and hemoglobin C. The third type is a combination of sickle cell with thalassemia, which accounts for many of the cases of sickle cell disease in Caucasians. In these combinations, a gene for sickling is derived from one parent and the gene for hemoglobin C or thalassemia comes from the other parent. Silvestroni and Bianco³ call attention to the combination in which one parent has sickle trait and the other thalassemia trait; the offspring may have a hemolytic disease which they term "microdepranocytosis." On the basis of genetic studies in 11 families, these authors are of the opinion that the genes for sicklemia and microcythemia (thalassemia) are inherited independently of one another and are located on different chromosomes.

Differential Diagnosis.—One must differentiate this disease from acute arthritis, osteomyelitis, acute abdominal conditions, organic heart disease, catarrhal jaundice, septic fever, syphilitic or varicose leg ulcers, and hemolytic anemias. The blood picture will usually put one on the right track for a correct diagnosis. In these cases the anemia is a hemolytic one. The cells do not show more fragility than is seen in normal cells.

The average age at death, according to Diggs, is eleven years. Life expectancy is less than thirty years. Death is usually due to a complication, such as tuberculosis, pneumonia, or sepsis.

Ovalocytosis

Ovalocytosis is a familial phenomenon characterized by large numbers of oval or elliptical red cells, which appears as a non-sex-linked Mendelian characteristic in certain individuals. The etiology is unknown. To date seventy-five authentic cases and twenty-five questionable cases have appeared in the literature. Dresbach⁴ described a patient in whom every red cell was of oval shape; the blood was otherwise normal. Bishop⁵ described a case in whom 75 per cent of the erythrocytes were oval, with the blood otherwise normal.

²Neel, J. V., Itano, H. A., and Lawrence, J. S.: *Blood* 8: 434, 1953.

³Silvestroni, E., and Bianco, I.: *Blood* 7: 429, 1952.

⁴Dresbach, M.: *Science* 21: 477, 1904.

⁵Bishop, F. W.: *Arch. Int. Med.* 14: 388, 1914.

Sydenstricker³ reported a case of a Negro with 90 per cent of his red cells oval. Lawrence⁴ reported a case of a white woman, 32 years of age, with many oval red blood cells. Bernhardt⁵ described the case of a white woman, 34 years of age, with oval red cells. Bernhardt termed this condition ovalocytosis. Miller and Lucas⁶ have reported nine additional cases, in four generations.

It must be understood that elliptical erythrocytes are not poikilocytes of any of the known anemias, including sickle cell anemia. It is a congenital anomaly compatible with an otherwise normal individual. It must be recalled that all mammals except the terrestrial family *Camelidae* show circular erythrocytes. Conversely, among the lower vertebrates, the red blood cells are elliptical with the single exception of the marine family *Cyclostomata*. Dresbach in 1902 first reported elliptical red blood cells in human beings. In the subsequent cases reported, it was found that males and females are equally affected. It has been observed in a number of different nationalities. Its familial tendency was proved by Hunter and Adams⁷ in 1929.

As stated above the etiology is unknown. It has been laid at the door of faulty erythropoiesis, influences of the blood plasma, the inherent quality of the cells, racial characteristics, anoxemia, and it has been suggested that the etiology is similar to that of sickle cell anemia. Normal erythrocytes are unaltered by the plasma of persons with this anomaly. By means of autopsy, bone marrow and splenic punctures, it has been shown that these cells are not elliptical when they are formed in the bone marrow, but assume that shape when subjected to the influence of some unknown constituent of the plasma or extramarrow tissues. That normal erythrocytes are unaffected by the plasma from a case of ovalocytosis suggests a second intraerythrocytic susceptibility to the extraerythrocytic influence, either or both of which may be congenital.

Miller and Lucas comment upon the fact that mechanical effects, temperature, normal blood serum, iso- and hypotonic saline washing, picric acid, carbon dioxide, oxygen, cholesterol, etc., all failed to affect the constancy of the ellipsoid state of the red cells. Terry has shown that elliptical erythrocytes are more resistant to hemolytic agents and have a decreased fragility. He⁸ has shown that these cells are heavier than round cells. Pollock and Dameshek⁹ observed that potassium cyanide increased the number of elliptical erythrocytes very rapidly.

The medicolegal point about this phenomenon is interesting; namely, within certain limits it may be used as a means of identification of both persons and paternity.

The cases reported by Miller and Lucas occurred in four generations. Twenty relatives were studied and none showed these elliptical cells. There were in this family five males and four females, varying in age from 30 days to 84 years, who had elliptical erythrocytes.

BONE MARROW

Since the above article was written there has appeared another family of three generations in which ten members exhibited elliptical cells. The report was made by Strauss and Daland.⁴

Motulsky and associates⁵ divide patients with hereditary elliptocytosis into four groups: (I) normal, round erythrocytes, (II) oval erythrocytes, (III) elliptical erythrocytes, and (IV) rod or cigar-shaped erythrocytes. They state that the predominance of group IV cells favors a diagnosis of hereditary ovalocytosis, whereas an association of elliptical cells and other deformed cells is more indicative of symptomatic ovalocytosis such as occurs with pernicious anemia, Cooley's anemia, severe iron deficiency, leukemia, cancer, and severe anemia associated with infection. In one of three cases presented, the survival time of transfused red cells was found reduced to 45 days. This case presented other evidence of hemolysis. On the other hand, the patients with normal survival times showed no hemolytic features. These authors call attention to the similarity of hereditary ovalocytosis with other diseases characterized by deformity of the red cell and shortened life span of these cells, such as occur in sickle cell anemia, hereditary spherocytosis, and thalassemia major. Just as in these syndromes, where there are a "disease" group and a nonsymptomatic "trait" group, ovalocytosis may likewise be subdivided. Red cell survival times in the trait group are normal, whereas in the disease group they are shortened. This survival time difference in the two groups is not dependent on elliptocytes; the cause for such differences remains unknown. Molecular disease of hemoglobin accounts for the changes in sickle cell, thalassemia, and other diseases, but electrophoretic studies in two of these three cases were normal and fetal hemoglobin was not increased. Motulsky and associates review the literature on symptomatology and heredity patterns in the hemolytic syndromes associated with erythrocyte shape anomaly and show the many points of resemblance between elliptocytosis and the other hemolytic groups. The hereditary pattern is considered a Mendelian dominant. Splenectomy is advised in the severe condition but not in the nonhemolytic or "compensated" form of the disease.

Target Cell Anemia

The term "target cell" was used by A. M. Barrett⁶ in 1938. These peculiar erythrocytes were described in a condition called "target cell anemia." This type of red cell, while described by Barrett, was really first alluded to as a special type of erythrocyte by Haden and Evans in 1937.⁷ They called them "dimpled corpuscles." Haden and Evans believed they were present only in sickle cell anemia but Barrett maintained that they were to be found in some cases of obstructive jaundice and severe hepatitis, in some cases of hypochromic anemia, and following splenectomy. In addition to this, Dameshek,⁸ described a case of target cell anemia, which corresponded to what he termed an "anerythroblastic type of Cooley's erythroblastic anemia."

⁴Strauss, M. B., and Daland, G. A.: Hereditary Ovalocytosis: Observations on Ten Cases in One Family, *New England J. Med.* 217: 100-103, 1937.

⁵Motulsky, A. G., Singer, K., Crosby, W. H., and Smith, V.: *Blood* 9: 57, 1954.

⁶Barrett: *A. M. J. Path. and Bacteriol.* 46: 604, 1938.

⁷*Arch. Int. Med.*, 1937.

⁸Dameshek, W.: *Am. J. M. Sc.* 200: 445, 1940.

The description of this cell, according to Dameshek, is about as follows: the cell is abnormally thin, tends to "buckle" and to present in stained preparations a bull's eye appearance. In contradistinction to the thick spherocyte, the target cells are unusually resistant to hypotonic solutions of sodium chloride. When these cells are present in any significant number (over 4 per cent) they result in a lengthening of the fragility span, with complete hemolysis occurring between 0.16 and 0.02 per cent, depending upon the number of these cells present. In the cases described, hemolysis was incomplete at a concentration of sodium chloride of 0.04 per cent. He found that by examination of the centrifuged red cells from concentrations of sodium chloride below 0.30 per cent, following resuspension in the patient's own (heparinized) plasma, the high concentration of target cells was demonstrated. When the red cells were suspended in varying concentrations of hypotonic solutions of sodium chloride and the hematocrits determined, they found in a concentration of 0.30, 45 per cent hematocrit, with mean corpuscular volume of 144. The target cell is the antithesis of the spherocyte.

Target cell anemia may be closely related to or indeed even a phase of the condition known as erythroblastic or Mediterranean anemia.

Dameshek for the first time reported a type of target cell anemia which he classified as *forme fruste* or an anerythroblastic type of Cooley's anemia or a closely related condition. This was an Italian youth with hypochromic anemia, splenomegaly, and a hemolytic type of icterus. About one-third of his red blood cells presented the appearance of "targets" or "bull's eyes"; these cells were unusually resistant to hypotonic solutions of sodium chloride. No nucleated red cells were present. Generalized osteoporotic changes with great thickening of the skull were present; in addition a bony tumor arising from a rib encroached on the right upper lung. Dameshek suggested the possibility that Cooley's anemia, sickle cell anemia, and target cell anemia are related conditions with target cells and increased saline resistance as common denominators. In Cooley's anemia, the target cell is probably a more fundamental abnormality than the erythroblast and may represent the basic hereditary defect. In these atypical hemolytic states, a lack of response to splenectomy further differentiates them from most cases of congenital and acquired hemolytic icterus.

Bohrod¹ believes that the target cell is a newly formed cell produced by the bone marrow in response to blood loss regardless of the cause. In support of this argument, he states that the appearance of target cells in the stained blood film, far from being an unusual event, is very common. Such cells can be found in small numbers, up to 1 per cent or 2 per cent, early in the majority of cases of anemia. Rare ones may even sometimes be seen in apparently normal spreads. In more chronic anemias the number is variable.

The presence of the target cells in stained spreads is transitory in acute anemia. They often disappear before there is a significant rise of the red cell count, in this way resembling the reticulocyte. In several cases they have been present for only one or two days. They usually first appear on the third or fourth day following a hemorrhage, although in one case they were first

¹Bohrod, M. G.: *Am. J. M. Sc.* 202: 869, 1941.

seen on the day after a hemorrhage from peptic ulcer. Coincident with their appearance there is a transitory decreased fragility of the erythrocytes. Bohrod cites the following cases:

Case Abstract.—

Case 1.—A woman, aged 23, lost considerable blood during and following the delivery of her second child. On the second postpartum day her erythrocyte count was 3,400,000, her hemoglobin 67% Sahli, color index 0.98. There were no target cells; the stained films appeared normal. The next day a few polychromatophilic erythrocytes were present and some of these were target cells. On the fourth and fifth postpartum days polychromatophilic cells were more numerous (between 1% and 2%) and nearly every one was a target cell. None of the normally stained cells were target cells, and a few target forms were seen in acidophilic cells. The important point is that *at one stage only those cells showed the target forms which by their polychromatophilia indicated their recent formation in response to the blood loss.* By the time of the patient's discharge from the hospital on the twelfth postpartum day the erythrocyte count was 4,100,000, hemoglobin 76%, color index 0.92. The stained film appeared normal; there were no polychromatophilic cells and no target cells.

In most cases target cells are seen only after a moderately severe hemorrhage. The loss of blood may be slight, as illustrated by the following case cited by Bohrod:

Case 2.—A woman received a laceration of the scalp in an automobile accident. Bleeding was, according to her, profuse, but it was stopped in about 45 minutes. No blood count was made until the fourth day later, when it was found to be 4,500,000; 2% of the erythrocytes were target cells. Three days later target cells had disappeared although the erythrocyte count had not changed.

Target cells are of normal diameter. In the stained spread they are made up of a rim of hemoglobin-containing area, with two areas being separated by a zone which is clear and unstained. Barrett believed that this appearance was due to a central knoblike projection in a cup or bowl-shaped cell and showed that a body of such shape would look like a target when viewed on the broad surface. That this is actually the shape of the cell can be seen by oblique illumination of dry films or in bas-relief photographs. No target cells are seen in wet preparations. Instead, a number of cells, equivalent to the proportion which appear as target cells in the stained film, appear as shallow or, more uncommonly, deep bowls or cups. When blood is diluted with hypotonic salt solutions of varying concentrations, the proportion of bowl-shaped cells, or of target cells in dry films, increases as the salt concentration decreases. This is due to the hemolysis of the normal-appearing cells and the preservation of the target cells.

Bohrod does not believe that the target cell is a fundamentally deficient cell in any type of anemia. He believes that the target cell is merely a hyper-resistant young cell which appears in the blood stream following loss of blood. He believes that in acute anemias they are present for only a short time early in the regenerative phase, and they have disappeared by the time a significant rise of erythrocyte count is evident. Also, he is convinced that the target cell is a hyperresistant cell produced by the bone marrow in response to the blood loss. Increased resistance to the hemolytic action of hypotonic saline and to acetic acid has been demonstrated.

Bohrod's views differ widely from those of Dameshek in that he does not believe that the contention that the target cell represents the fundamental

defect in Cooley's anemia is justified. It is simpler, in Bohrod's opinion, in light of available evidence, to regard the target cell in this disease, as in sickle cell anemia and in many other anemias, as a response to the blood destruction rather than as the cause of it.

Since the last edition of this text, a great deal of work has been done in diseases associated with the target cells. Much of this material is covered in the section on "Molecular Disease of Hemoglobin," pages 734 ff. *Thalassemia major* has been designated the symptomatic form, with marked anemia, hemolytic crises, and numerous target cells (see page 731). In this condition, Singer and his co-workers have demonstrated high fetal hemoglobin values ranging from 40 to 100 per cent. The trait state, *thalassemia minor*, may be found in members of the family of patients with the disease. These individuals are asymptomatic but have target cells in small numbers in their blood. Fetal hemoglobin in the trait group may be increased up to 10 per cent. Since these original publications, *thalassemia* has been described in conjunction with other molecular diseases of hemoglobin. These combinations include sickle-thalassemia disease, *thalassemia-hemoglobin C* disease, and *thalassemia-hemoglobin E* disease.

The mode of inheritance of *thalassemia*¹ reveals that both parents of such patients are heterozygous, but a homozygous combination of the pathologic genes results in offspring displaying severe hemolytic disease. The heterozygous group usually have no hemolytic phenomena and a normal red cell survival time, as compared with a shortened survival time in the homozygous state. Eadie and Brown² believe that the shortened life span is due to random destruction of cells.

Aplastic Anemia

Aplastic anemia is usually regarded as a well-defined, readily recognizable clinical entity, with features that are the result of a progressive depression and final cessation of bone marrow activity and aplasia of this tissue. Ordinarily, one does not think of regeneration in these cases, but Thompson, Richter and Edsall³ reported thirteen cases of aplastic anemia in which there was evidence of blood regeneration. The first case of aplastic anemia on record is that by Ehrlich.⁴ In this case the red count was 213,000, no white count reported, no blood platelets reported, tibial marrow yellow and fatty. By 1908 Cabot⁵ collected 24 cases and Hirschfeld,⁶ in 1911, found the total to be 44. Musser⁷ reviewed the situation up to 1914. In 1919, Smith collected 64 cases. He found that it was a disease of young adults that progressed rapidly and it was characterized by a progressive decrease in the number of formed elements in the blood. Root⁸ and Carey and Taylor collected, in 1931, 150 cases.

It is accepted that idiopathic aplastic anemia is a uniformly acute, rapidly fatal disease of adolescents and young adults, with a high fever, a rapid decrease in the cells of the blood with very little suggestion of regeneration of the blood cells. At autopsy, the bone marrow shows complete fatty degeneration.

The blood picture is a lowered count, often below 2,000,000; a marked lowering of hemoglobin with the color index usually below 1.0. While there is a rapid decline in the number of red cells, the form of the cells is not markedly changed. It is significant that there are no nucleated red cells and very little polychromasia. Reticulocytes are very scarce. The white cell count declines with a decline of the neutrophils and disappearance of eosinophiles, and a relative lymphocytosis supervenes. There is a marked leukopenia in advanced cases of this disease. The final picture, so far as leukocytes are concerned, is practically all lymphocytes. Another very characteristic phenomenon in the blood picture is the decline and the absence of blood platelets. It is significant that when the blood platelets drop very low, purpuric symptoms occur.

From a study of the literature, it seems that there are three variants of aplastic anemia. There are cases in which the disease is acute in its course, without evidence of regeneration, and with a complete aplasia of the marrow at autopsy. In addition, there is a second group comprising a few cases with clinical features similar to the preceding group, but in which the marrow, instead of being fatty, was found to have a normal or even increased cellular content. Such cases have been reported by Naegeli,² Senator,³ Wolff,⁴ and Root⁵ and several appear in the Italian literature⁶⁻⁸ under the name of "pseudoplastic anemia," a term suggested by Luzzatto⁸ to indicate the discrepancy between the blood and bone marrow picture. The third variation includes progressive hypocythemia cases in which evidence of regeneration appeared in the peripheral blood.

According to Thompson, Richter, and Edsall, examination of the peripheral blood may be no index as to the morphologic appearance of bone marrow examined, and the morphologic appearance of the bone marrow may be no index as to its functional activity. There may be quite serious interference with the normal course of development, maturation, and division of blood cells without alteration in the cellular content of the marrow.

Krumbhaar in commenting upon the case reports and conclusions of Thompson, Richter, and Edsall, stated very properly that these conditions should be described by three different labels as follows: "aplastic anemia" is a term to be reserved for the type without evidence of regeneration in blood or bone marrow; "pseudoaplastic anemia" for the variety with cellular bone marrow; and "progressive hypocythemia" for the cases corresponding to those of Thompson, Richter, and Edsall where there is an evidence of attempted regeneration in both bone marrow and blood.

Hookworm Anemia

Hookworm anemia has been known since the construction of the Gotthard tunnel in Switzerland in the years 1876-1880. Perroncito¹ noted that many Italian workers developed a severe and at times fatal anemia, with hookworm infestation. Later, hookworm anemia was called miner's anemia because of its occurrence in mines. Boycott² described cases of hookworm anemia in England (1901). Later hookworm anemia was observed in other European countries, in America, and in tropical countries, where suitable conditions for hookworm infestation exist.

The etiology of this disease has been well discussed in many papers. Stransky and Quintos³ gave an accurate description of it from their experience in the Philippines, where the *Ancylostoma* is very common.

They observed three types or stages of blood changes in hookworm disease. In the first type the bone marrow is able to maintain the equilibrium between blood loss and production, and there is no manifest anemia. They call this the stage of "compensated anemia." In the second type the production is unable to counterbalance the blood loss, and a hypochromic anemia results. In the third type the bone marrow is exhausted, and aplastic anemia develops. In the first type they found in the peripheral blood eosinophilia and reticulocytosis without anemia. The bone marrow findings were characterized by increased erythropoietic activity and likewise eosinophilia. Despite a continuous loss of blood, an increased production in the bone marrow was sufficient to maintain the equilibrium between blood formation and blood loss. In the early stage of hookworm disease, real anemia may not develop if food and living conditions are adequate.

In the second type, they described these characteristics—anemia, microcytosis, hypochromia, eosinophilia, and reticulocytosis in the peripheral blood; and eosinophilia and marked erythropoietic activity of the bone marrow.

Hookworm anemia is hypochromic and microcytic, with a red cell count of 1.0 to 3.5 millions per cubic millimeter. In advanced cases the red cell count may drop to below one million. Eosinophilia usually amounts to from 5 to 15 per cent, although in more advanced cases eosinophilia may no longer be present. In some cases there may be a hypoplastic tendency of the bone marrow, but the condition is still reversible and the patient recovers.

The third type, or irreversible type (aplastic anemia), is characterized clinically by severe anemia, dizziness, easy fatigability, and hemorrhagic diathesis. The erythropoietic activity of the bone marrow is almost nil. There is so-called panmyelophthisis with low cell count; relative lymphocytosis; and lack of erythropoietic, granulocytopoietic, and thrombocytopoietic activity of the bone marrow. In this stage antihelminthic and antianemic treatments are of no avail. Blood transfusions and iron are ineffective in improving the irreversible process. Aplastic anemia as a possible outcome of hookworm infestation has only rarely been mentioned. Stransky and Quintos observed eight cases of aplastic anemia in hookworm disease. They observed during the same time five so-called primary idiopathic aplastic anemias. In one case there were

hypochromia, anemia, leukopenia with granulocytopenia, and relative lymphocytosis, thrombocytopenia, and reticulocytopenia in the peripheral blood. There were low cell count, relative lymphocytosis, poor erythropoietic activity, and megakaryocytopenia in the bone marrow. In two other cases, while the outcome was the same as aplastic anemia, the hematologic picture at first was not definitely that of panmyelophthisis. One of these cases was an example of severe anemia with symptoms of early hemorrhagic diathesis. From the hematologic picture alone, the diagnosis of aplastic anemia could not be definitely made during the stay of the patient in the hospital for seven weeks. However, the outcome was fatal, and in two weeks after discharge, there was probably a rapid breakdown of the bone marrow. In another case, anemia was not extreme at first, with a count above one million; bone marrow count was 105,000, which is about normal, and the differential count was not much altered; but the erythropoietic activity of the bone marrow was low, the ratio of nucleated red cells to white cells was 0.19:1.0 compared to 0.3:1.0; 0.6:1.0; and 1.1:1.0 in those that recovered in the second type. The hemorrhagic symptoms, leukopenia with relative lymphocytosis, thrombocytopenia, low reticulocyte count, and absence of nucleated red cells in spite of the anemia, shown by the peripheral blood, were in favor of aplastic anemia even in the beginning of the observation, despite the somewhat normal bone marrow findings. They believed that their cases of aplastic anemia were not simply coincidental with hookworm anemia but were actually related to it. They believed that the aplastic anemia of hookworm disease is due to bone marrow exhaustion following continuous blood loss in the presence of various factors, including dietary deficiency.

Hematology of Lead Poisoning

The effects of alimentary, respiratory, or cutaneous contact of lead with the human body lead to a definite change in the microscopic picture of the red blood cells; in the main, the appearance of the classical basophilic punctation and a mild degree of polychromasia. These changes in the blood are the first and most striking signs of lead poisoning in man. Hematology is indebted to the work of Aub, Reznikoff, and Smith¹ for definite information on just how lead acts specifically upon the blood system. Their experiments in vitro with blood and lead demonstrate two sets of facts: first, the physiologic, physical, and chemical reactions of lead on isolated cells, indicating a similar action on other body cells; and second, the production of at least one type of secondary anemia. The experimental researches by Aub, Reznikoff, and Smith, and P. Schmidt² serve to guide one in understanding the effects of lead upon the human system, although the complete story has not by any means been written.

According to Aub and others, Laennec³ first recognized lead anemia in man. Exposure of experimental animals to lead is followed by marked anemia. This was demonstrated in rabbits by intramuscular injection by Carcanaque and Maurel⁴ and after oral administration by Key.⁵

Two causes of this anemia have been described: marked destruction of blood, or a lesion in the bone marrow with consequent deficient blood formation. According to Stockman and Charteris,¹ and Raimondi,² bone marrow of rabbits showed a marked preliminary increase of leukoblasts with disappearance of fat, followed later by definite gelatinous degeneration. Wolff³ described a case of severe lead poisoning in which attempts to regenerate blood were followed by deficient hematopoietic function, as seen in the bone marrow. Meillère,⁴ Schnitter,⁵ and Sellers⁶ thought that lead definitely injured both blood cells and bone marrow. Bouchard,⁷ and later Rauch⁸ and others, attributed the primary appearance of anemia to abnormal destruction of the cells in the circulation, even though degeneration of the bone marrow may occur later. Evidence for this is diverse. Early lead poisoning shows hyperplasia of the bone marrow⁹ with many nucleated red cells in the circulation which seem to indicate regeneration. Key¹⁰ demonstrated that within 24 hours after ingestion of 1 gm. of lead the number of circulating erythrocytes in rabbits decreased more than 20 per cent, with the appearance of many nucleated red cells. Meillère¹¹ showed a definite increase in urinary excretion of iron, largely derived from erythrocytes, in the onset of lead anemia. J. W. S. Brady,¹² in Aub's laboratory, demonstrated that slow intravenous injection of lead acetate dissolved in saline caused marked hematuria and very marked increase in excretion of bile pigments from the common duct. These unpublished experiments on rabbits indicate definitely and very clearly that small quantities of lead in the blood stream cause great destruction of blood, not accounted for by any osmotic changes. Chester Jones¹³ obtained similar evidence in human cases. He showed that both the blood plasma and bile obtained by duodenal drainage from several cases of plumbism contained very high concentrations of bile pigments. These facts indicate marked peripheral destruction of blood due to ingestion of lead. No good explanation of this increased blood destruction has been previously suggested because of the lack of thorough experimentation upon the subject.

Observations of several phenomena associated with the blood in lead poisoning have been made. Behrend¹⁴ in 1899 first observed the stippling of erythrocytes in lead poisoning. Key¹⁵ in 1922 summarized the many reports appearing in the literature since Behrend's observation. It is probable that stippled erythrocytes are really young red cells degenerating as a result of exposure to lead. Since stippling cannot be produced in vitro¹⁶ the mechanism of their development is not yet understood.

Erythrocytes in lead poisoning show increased resistance to hemolysis in dilute saline solution. Malassez¹⁴ reported in 1873 that not only is anemia a symptom of lead poisoning, but that the erythrocytes are larger and more fixed than normal. Agasse-Lafont and Heim¹⁵ found slightly increased globular resistance in lead poisoning. Von Liebermann,¹⁶ and later Orban¹⁷ and Hayhurst¹⁸ demonstrated this. Fici¹⁹ studied this reaction in vitro in 1921 and found that lead acetate exerts a striking effect on the hemolysis of red cells in hypotonic saline solutions, varying with concentration of lead and with temperature.

Fici's observations have been confirmed by the work of Aub, Reznikoff, and Smith. It appears, from the investigations of other laboratories, that the anemia observed in cases of lead poisoning is due to *destruction of blood* rather than to *diminished production of blood*. The method of poisoning cells in vitro with lead was adopted by Aub and his coworkers in order to study this phenomenon, and distinct effects were thereby obtained, even when only 0.001 mg. of lead is added to approximately 5 billion washed red corpuscles. In order to obtain optimum results the usual dosage employed was ten times this or 0.01 mg. per 5 billion cells. After this exposure, they noted the following changes in the cells treated: such a marked increase in the resistance to hypotonic salt solution developed that complete hemolysis did not occur until the cells were exposed to a saline solution of 0.05 per cent. Untreated cells were completely hemolyzed in 0.25 or 0.225 per cent saline. This reaction was quantitative and varied with the concentration of lead used. Under the conditions of the experiments this phenomenon seemed to be unique. The effects of arsenic were very slight in comparison. While from this reaction it may be concluded that lead increased cellular resistance, it also appeared that it shortened the life of blood cells. This may be demonstrated by the much more rapid appearance of hemolysis than normal when the cells were merely allowed to stand in Ringer solution of any dilution. In rabbits with acute lead poisoning these same phenomena were noted in vivo. Both phenomena may be changed in vitro by varying the time and temperature of the reaction and the concentration of lead, as Fici has already pointed out. If normal cells stood in Ringer solution for six hours, something diffused into the solution which largely reduced the action of lead. After repeated washing these cells reacted with lead in the usual manner. Small amounts of serum reacted with lead and eliminated its effects. Red blood cells, treated with a mixture of lead and blood serum, showed normal hemolysis in hypotonic salt solution. When lead was added to whole blood, the only evidence of this neutralization was a marked decrease in the intensity of the reaction. This is probably explained by the fact that since both serum and cells were present together, the lead reacted with both simultaneously. This in turn explains how the reaction may occur in vivo. The change in hemolysis

does not appear in the blood of all species of animals. In the species in which it does occur, anemia and stippling of the red cells also tended to develop readily during lead intoxication. In vitro, cells which have been exposed to lead were far more fragile than normal blood cells. Slight trauma caused them to hemolyze. In vivo this was probably an important causal factor in the increased destruction of blood and in the anemia of acute lead poisoning. The serum of a rabbit, which has been immunized to human blood, caused more rapid and complete hemolysis in cells treated with lead than in the control cells. No satisfactory explanation for this has been found.

Further studies by Aub, Reznikoff, and Smith¹ on the effects of lead on red blood cells so far as surface phenomena and their physiologic explanation were concerned, showed the following: partial loss of the normal stickiness of red corpuscles, which was demonstrated by their falling from a clean glass surface; loss of the agglutination reaction which normally followed mixture with serum of a different isoagglutinating group; decrease in volume even in isotonic solutions; loss of normal elasticity and, therefore, reduced changes in volume upon exposure to marked variations in osmotic tension; increase in resistance to large changes in external osmotic pressure because of this inelasticity, and therefore decreased hemolysis in hypotonic salt solution; increase in the speed of disintegration in spite of this increased resistance to external osmotic pressure. "Leaded" cells broke up more readily upon standing than did normal cells, and were easily fractured by rotation or shaking.

All these phenomena seemed to be associated largely with surface changes in the corpuscles. Evidence was cited that there was no chemical reaction between lead and hemoglobin. The gas exchange was identical in normal and "leaded" cells. The function of the interior of the red cells, therefore, appeared to be unaffected by lead.

The effects of lead upon red blood cells were thus manifested by shrinkage, inability to expand, increased brittleness, and loss of the normal consistency which made their surface sticky. After exposure to lead, red blood corpuscles were more like hard inelastic brittle rubber balls, than like the soft, elastic, resilient cells characteristic of normal blood.

A third communication by Aub and Reznikoff* gave a very comprehensive chemical explanation of the reaction of lead with red blood cells. They showed that the changes in red blood cells caused by lead were explained on the basis of the union of lead with inorganic phosphate and were largely surface phenomena. It was found by them that lecithin, cholesterol, euglobulin, pseudoglobulin, hemoglobin, and albumin do not interfere with the reaction. Sodium bicarbonate can neutralize lead; but ten times as much is required as occurs in an equivalent neutralizing quantity of serum. This carbonate can therefore play only a small role in the reaction. They found that inorganic phosphate in the same concentration as is present normally in serum neutralizes the same quantity of lead as does the whole serum itself. This can, therefore, completely account for the action of lead on red blood

*J. Exper. Med. 40: 189, 1924.

¹Aub, J. C., Reznikoff, P., and Smith, D. E.: J. Exper. Med. 40: 186, 1924.

cells. Adding inorganic phosphate to red blood cells or to whole blood greatly decreases the action of lead on the cells but cannot eliminate it completely. This indicates that there is a simultaneous reaction between lead and serum and lead and corpuscles when all are present, and explains the action of lead in vivo. Serum with increased inorganic phosphate content, obtained from two patients, neutralized the effect of lead to a high degree. In one case serum with a high normal phosphorus content had a similar though less marked action.

They concluded further that diffusion of inorganic phosphate from erythrocytes into the surrounding Ringer solution prevents the action of lead upon the corpuscles, due to neutralization of the lead by the diffusate. If the diffusate is washed from these same cells, lead will again react with them. These findings indicate that the union of lead with the inorganic phosphate of the cells explains the action of lead on erythrocytes. Interaction of lead salts and phosphate results in the formation of a very insoluble lead phosphate $[Pb_3(PO_4)_2]$ and free acid (Fairhall). When a collodion membrane separates solutions of lead chloride and phosphate or serum, lead phosphate is precipitated in the membrane with a local formation of acid. This acid, formed as the result of the union of lead and phosphate, may perhaps change the physicochemical state of the colloids of the cell surface. Macroscopic cataphoresis determinations demonstrated no difference between migration of "leaded" and normal cells. Agglutination experiments with colloidal iron and arsenic showed a marked difference between "leaded" and normal cells. All this points to further evidence of changes in cell surface.

The three papers by Aub and Reznikoff suffice to explain the anemia of lead poisoning. Red cells in vitro showed various changes after exposure to a very small amount of lead. The surface of the cells is changed. Their permeability to water is so altered that they shrink and are incapable of swelling as much as normal cells. This is associated with a marked increase in resistance to different osmotic surroundings. They show less hemolysis than normal in very weak salt solutions. "Leaded" cells hemolyze readily as a result of slight trauma and are very short lived. These cells also lose their normal stickiness and are no longer agglutinated by sera of incompatible isoagglutinating groups. These changes are evidences of an effect on the surface of the cell, not the interior, which does not undergo disturbances, at least insofar as the physiologic properties of the hemoglobin are concerned. These physical changes are brought about by a precipitation of insoluble lead phosphate and a formation of acid, causing the "leaded" erythrocyte to change from an elastic distensible sac to one which is contracted, relatively inelastic and brittle. This altered cell cannot withstand the trauma involved in the circulation of the blood, which probably explains the marked destruction of peripheral blood in lead poisoning.

It is believed that basophilic punctation is an effect of lead, but the presence of basophilic punctation alone does not prove the case. One must have history, clinical symptoms such as lead colic, the lead line on the gums, the finding of lead in the urine, etc.; all these serve to clinch the picture. P. Schmidt has well said that basophilic punctation is a "valuable aid before the appear-

ance of other symptoms." There is a marked tendency today, with this disease entering into court circles, for litigants to attempt to convince juries, judges, and Workmen's Compensation Boards that the finding of basophilic punctation and polychromasia is proof positive of a case of lead poisoning or vice versa. It is fair to assume in these cases that in addition to basophilia, the entire blood picture must be studied and weighed in the balance, as well as the clinical symptoms, before accurate conclusions may be drawn.

As evidence of the abnormal pigment metabolism related to hemoglobin in lead exposed workers, Bashour and Watson* have demonstrated increased excretion of urinary coproporphyrin and uroporphyrin, as well as the presence of porphobilinogen.

Leukocytic Picture in Lead Poisoning.—Thiele,¹ Seiffert,² and Seitz³ studied the effects of lead on the white blood cells. Thiele claimed that the lymphocytes are destroyed, but this was denied by Seiffert. On the contrary, Seitz called attention to the lymphocytosis in lead poisoning: this has been confirmed by Thiele, Stickl,⁴ Legge-Godbay, Baader⁵ and others. Schmidt-Kehl⁶ noted lymphocytosis in self-experimental work. Stickl⁴ noted also a monocytosis. Nestsadimenko and Volkow⁷ claim that there is a left shift of the neutrophiles. These findings are inconclusive: *we have no justification for describing a characteristic leukocytic picture in lead poisoning.* Since we appreciate fully that the human organism, when afflicted with lead poisoning, must be under the stress of severe nerve and endocrine insult, we may assume that the consequent leukocytic blood picture changes are referable to tissue reactions of this type; an early slight nuclear shift may be due to a toxic irritation by lead; a lymphocytosis and even a monocytosis may be due to a plumbic injury of the myelocytic system. So, too, may we understand the occasional and irregular eosinophilia that has been described by certain workers as characteristic of plumbism. As a matter of fact, Selig⁸ claimed that eosinophilia which he observed in lead poisoning (as high as 70 per cent) was due to a vagus injury.

Erythrocytic Picture of Lead Poisoning.—In addition to the basophilic punctation and polychromasia, it is generally believed that there is a general anemia present in lead poisoning. This was well explained by Aub and Reznikoff. This anemia, however, is not nearly as severe as is generally believed. Teleky⁹ reported hemoglobin percentages from 70 to 80 per cent. Seitz reported a number of cases³ but not more than a fourth of them had hemoglobin less than 80 per cent. That hyperchromemia is a part of lead poisoning has been asserted by some and denied by others. There is no evidence that lead poisoning can produce a hyperchromatic megalocytosis. According to

Naegeli¹ the smallest number of red cells found in a case of plumbism was 3,500,000 by Becker; 3,700,000 by Malassez; 2,200,000 by Limbeck. In his own 300 cases, Naegeli found one case with 50 per cent hemoglobin, 2,832,000 reds, 12,800 whites. Levin² calls attention to one case with hyperchromemia, 65 per cent hemoglobin, 2,800,000 reds, and a color index of 1.16.

The momentous points to be settled in dealing with lead cases are—is there some factor other than lead that can explain the condition present? Second, are all the findings compatible with the effects of lead; are lead effects standardized, pathognomonic and not seen in any other condition? In answering these questions, one must have *more than the blood picture* in order to come to a final conclusion; namely, history, clinical symptoms, and perhaps chemical findings.

It must be conceded in reviewing the effects of lead upon the body that the bone marrow is vitally affected, as proved by the results of experimental research of Aub,³ Speransky and Shlianskaya,⁴ Seiffert and Arnold⁵ and others. Speransky and Shlianskaya noted an increased number of erythroblasts and a disturbed leukopoiesis in guinea pigs. Seiffert and Arnold call attention to the increase in the larger erythroblasts with increasing but abnormal regeneration. Schmidt and Barth⁶ found the largest amount of lead in the body always accumulated in the trabeculae and not in the bone marrow. This was confirmed by Aub³ and his co-worker Fairhall. In Schmidt and Barth's research, there was found a necrobiosis of the nuclei. The lead was found bound by the nuclei. They thought they were on the way to prove that basophilia was of karyogenous origin, but later work by others on bone marrow punctures with the use of combined Wright and Giemsa stains showed perfect nuclear structures with equally perfect basophilic punctation in the cytoplasm. It seems rather dubious to believe that basophilic punctation is a resultant of nuclear disintegration. We stand between the thought that polychromatic and basophilic punctated material is a property of many young cells, and also that young regenerative cells of all kinds may perish in the bone marrow as a result of toxic impressions.

In an attempt to clarify the obscurity of the classification of the plumbic anemia, Ucko and Duesberg⁷ suggest that lead anemia belongs to a special category: "an anemia with disturbed regeneration and formation of porphyrin." They would place lead anemia with pernicious anemia, sharply differentiating it from the methemoglobin-forming and hemolytic anemias. One must classify lead anemia as a toxic central disturbed erythropoietic phenomenon, related to special blood diseases of infection, intoxication, and systemic injury. It must be considered apart from the symptomatic simple anemias because of its degenerative tendencies.

Attention must be called to the fact that the effects of lead on the blood persists long after chemical tests would avail in making the diagnosis, thus

adding another pitfall in the path of exact diagnosis. These considerations must be carefully weighed in forensic determinations.

Schilling has done much to demonstrate that technic in preparation of blood specimens is a more important factor than was heretofore believed, in clinching the diagnosis of lead poisoning. Ordinary spreads do not suffice. One must incorporate into routine practice *the making of thick drops in all cases*. There is frequently a marked discrepancy between data from spreads and those from thick drops. In a number of cases here in St. Louis where forensic considerations required examination of the same individual by different workers, we have seen otherwise good and honest testimony weakened by failure to make thick drop examinations in suspected lead cases. Spreads fail to show characteristic basophilic punctation and polychromasia often where thick drops give undeniable evidence of this kind. In 1924 Koch¹ urged that a standard method of staining should be worked out for these cases. For blood films, possibly the Schwarz² modification of the Manson method is the method of choice (page 619). As a matter of fact, the Giemsa and Wright methods of staining ordinary blood films suffice quite well to demonstrate basophilic punctation and polychromasia, as well as all other components of the blood picture.

The **supravital methods of staining** are admirable for the demonstration of basophilic punctation.

The **thick drop method** of Schilling is the best method of demonstrating basophilic punctation and polychromasia in lead poisoning (see page 650). This method, originally introduced by Ross for the demonstration of malarial parasites, is now widely used in lead poisoning studies. An observation of the central part of the drop will show the different degrees of basophilia present.

The average blood picture in lead poisoning would be: P and BP + + +, medium to coarse, torn. Hemolytic icterus: P + + + +, fine to coarse.

There has been some controversy as to just how to interpret this basophilic punctation in blood films and in thick drops. Brueckner claims that no special significance may be attributed to basophilic punctation as compared with polychromasia and that the coarser forms of basophilic punctation are simply younger and perhaps more activated cell forms. Weight of opinion, however, seems to point to the fact that polychromasia and basophilic punctation are quite different. Polychromasia is found in marked degree in many conditions, under an endless variety of pathologic conditions, even in supposedly healthy persons who are probably under the influence of a slowly developing occult chronic illness. Basophilic punctation, on the other hand, is found only in very severe toxic anemias due to blood poisoning in various forms, protozoal disease, purpura, pernicious anemia, leukemia, and aplastic anemia. In other words, it is an entity due to a very definite and serious condition. Where one can reasonably believe that no malaria exists, the first thought in finding a very pronounced state of basophilic punctation in the thick drop or film would be lead poisoning, or poisoning with benzol, arsenic, or with any one of the heavy metals. An objection has been raised to this conclusion by those who have studied the guinea pig experiments

¹Koch: Arch. f. Hyg. 94: 306, 1924.

²Schwarz: Klin. Wchnschr., Heft 44, 1922.

of Lehmann,^{1, 2} but one must remember that guinea pigs and man are quite different, that guinea pigs are quite sensitive and have been known to develop basophilic punctation from poor housing conditions. It must be mentioned here, however, that Konrich³ and Lehmann² report basophilic punctation in cement workers. Jötten and Scharlau⁴ failed to find basophilic punctation in workers in dusty occupations.

The McCord basophilic aggregation test in lead poisoning does not give as much information as the reticulocyte count and is less accurate, and so it has been omitted from this edition.

Summary

Lead poisoning is an acute disease characterized by symptoms involving three systems: namely, the gastroenteric, hematopoietic, and the nervous systems. Rarely the latter may appear to be exempt; the former two never.

Acute episodes may recur and give a false appearance of chronicity. Sequelae also may persist for long periods. Signs of abnormal lead absorption are mistakenly considered to represent illness.

The cure of the disease depends on the cessation of hazardous exposure and the elimination of toxic quantities of lead from the body.

Kehoe⁵ emphasizes this need for prophylaxis and decries the lack of proper preventive measures as indicated by the great number of cases of lead intoxication that still exist. He particularly sounds a note of warning concerning the use or possible "misuse" of the newest agent in the treatment of lead intoxication, namely, calcium disodium versenate (ethylenediamine-tetraacetic acid, EDTA). Kehoe calls attention to the long list of substances which have been used in the past to mitigate the effects of excessive absorp-

TABLE 56.—LEAD LEVELS* IN HEALTH AND IN VARIOUS INDUSTRIES

tion of lead, such as milk, ascorbic acid, laxatives and purgatives with lemonade fortified by acid. Although the new derivatives of edathamil appear to have the property of combining with lead in the soft tissues and then being excreted in the urine, it has not been established that it is lifesaving or that it can be relied upon to relieve symptoms. For the relief of colic Vigliani² recommends that cortisone or corticotropin be administered along with drugs which either neutralize or eliminate lead from the body. Belknap and Perry³ recommended the combination of intravenous calcium gluconate and edathamil calcium disodium for the treatment of lead colic.

Vital Signs and Clinical Laboratory Data:

Temperature, 98.4° F. Pulse, 80. Respiration, 22. Blood Pressure, 132/79. Red Blood Count, 4,270,000. White Blood Count, 7,550. Hemoglobin, 11.4 gm. Urine—occasional cast.

Effects of Other Chemicals on the Normal Blood Picture

In addition to lead, the blood picture may be altered by other chemical substances. Acetanilid, acetphenetidin, and other aniline derivatives produce anemia. Stengel and White¹ reported a case of chronic acetanilid poisoning and severe anemia with red cells 2,000,000 and hemoglobin 35 per cent. There were present a great many normoblasts with many variations in the size and shape of the red cells.

Arsenic in small amounts over a long period of time causes a mild stimulation of hematopoiesis. When arsenic is ingested in toxic amounts, there is a reduction in the granular leukocytes and actual leukopenia may occur.

Arsphenamine in exceptional cases has produced an effect upon the bone marrow very similar to that seen in aplastic anemia or purpura hemorrhagica. This effect may be fatal.

Carbon monoxide produces secondary anemia. In acute poisoning, the hemoglobin changes to methemoglobin.

Nitrobenzene, or shoe dye poisoning, has been seen frequently. It is not at all certain that the union of the poison with hemoglobin produces methemoglobin, so that the term "pseudomethemoglobinemia" has been devised by Peters and Van Slyke² for this condition. There are no changes in the morphology of the red cells.

*From a statistical analysis of 30 cases.

Poisoning by Benzol and Related Products

Benzol is a volatile inflammable fluid, used in industry for cleaning printing rooms and engraving plates, in rubber cements, in lacquers, varnishes, and for many other purposes, it being an excellent solvent for rubber, gums, fats, and resins.

Acute poisoning is often due to breathing excessively large amounts of benzol vapors. This may be rapidly fatal. Acute poisoning more often occurs as a result of an accident, such as the bursting of a pipe line, the overflow of a large tank, or workmen entering a tank for cleaning or repair work without using proper protective measures.

Chronic poisoning differs from the acute type in that benzol is inhaled in small quantities over a considerable period of time, the chief effects being observed in blood and blood-forming organs. It is a slow process and the early stages and symptoms are not striking. Later, the symptoms increase, and if the case is not recognized and exposure continues, serious poisoning may develop, which, in advanced cases, may produce death.

Acute poisonings, for instance, deaths in garages, poisoning in tanks, due to benzol (Marienfeld² and Zangger³) show no specific hematologic change. The subacute and the chronic benzol poisoning are suggestive of idiopathic blood diseases, and it is very difficult to distinguish them from thrombopenic diseases, such as Werlhof's purpura, agranulocytosis, aplastic anemia, aleukia, panmyelophthisis, etc.

The first communication on this subject was made by Santesson,⁴ who reported four fatal cases of women workers in a velocipede factory; all four cases were among young women workers.

CASE 1.—Eighteen-year-old girl worked only three weeks in the factory, became sick with fever, pulse 120, and had severe anemia with hemorrhagic tendency. Death followed after several weeks while she was sitting at her work. At autopsy nearly all the organs showed small or large hemorrhages.

CASE 2.—A woman, aged 20 years, who worked four months in the factory, showed first signs of hemorrhagic tendency before giving up her work. She came down with severe bleeding from teeth and nose and vomited blood. Death followed with a severe anemia one week after she went to bed.

CASE 3.—Nineteen-year-old woman worker, who worked two months in the factory, showed hemorrhagic diathesis for three weeks. Her hemoglobin dropped to 20% and red cells to 600,000. Four to five weeks after quitting work, the patient died with outspoken hemorrhagic tendencies.

CASE 4.—Nineteen-year-old woman worker had worked four weeks in the factory. There was a severe leukopenia with hemoglobin of 80%, red cells 3,764,000. Death occurred, with symptoms of hemorrhagic diathesis, one and one-half months after quitting work.

All these cases began clinically with the hemorrhagic diathesis of the skin, blue spots, hemorrhages from the gums and nose, and sometimes intestinal bleeding. In other words, a picture of purpura was seen in all cases.

²Marienfeld: *Ärzt. Sachverständigen-Ztg.*, Bd. 34, 1928.

³Zangger: *Deutsche med. Wchnschr.*, 1929.

⁴Santesson: *Arch. f. Hyg.* Vol. 31, 1897.

Santesson noted that with pure benzine experimentally, no results were obtained, while with benzol (benzene), the same result was seen as in these four cases. In the autopsy material a study showed that severe endothelial fatty changes were responsible for the bleeding. Santesson believed that there was a central disturbance, which was first noted by Selling¹ whose clinical experimental work has been noted so often in the literature. Santesson reported two girls with chronic benzol poisoning, the first showing 640,000 erythrocytes and 8% hemoglobin. There was a severe thrombocytopenia. In the second case there were 1,150,000 erythrocytes with 15% hemoglobin and no regenerative forms.

Selling states that thorium X and benzol act upon the bone marrow as poison, leading to severe cellular diminution in the bone marrow substance, that is, deprivation of the specific parenchymatous cells. The erythroblasts and myeloblasts are disturbed, while the peripheral red cells are also destroyed. There is a slight aplasia of the lymphatic organ. The lymphocytes in the peripheral circulation and the polyblasts in the tissues seem to be most resistant to the actual poison. We find very few myelocytes and normoblasts in the circulation. We find usually severe leukopenia. After daily injections of from 0.5 to 3 c.c. of benzol in rabbits, in six to ten days the leukocytes practically disappeared. The blood picture became composed almost entirely of lymphocytes and monocytes which were absolutely decreased, relatively naturally increased. Selling,² as well as Pappenheim,³ spoke of the peripheral solution of blood. Veit⁴ established a degenerative disturbance of the lymph centers while Pappenheim had noticed an irritation in the parenchyma of the lymph tissue. Neumann⁵ described marked differences experimentally among various poisons. He found in the bone marrow a failure of myelocytes and giant cells but saw areas of pigment composed of destroyed erythrophages, and a definite aplasia of the malpighian corpuscles in the spleen. Later these researches were taken up with better technic by Silberberg,⁶ Woronow,⁷ and Orzechowski.⁸ Silberberg found in rabbits an absolute leukopenia after giving 3 c.c. of benzol subcutaneously.

A few monocytes are found in the blood picture. Woronow noted an aleukia on the seventh to eleventh days, otherwise about 300 to 500 leukocytes in severe cases. Selling spoke of hyperleukocytoses which other workers after him did not establish. Shortly before death in experimental rabbits Woronow noted a liberation of from 10,000 to 15,000 leukocytes, then, right before death, a neutropenia.

These differences in the results are due either to differences in the individualities of the patients, or animals, or because there were some poisons with impure benzol, that is, xylol or toluol, etc. Woronow established that with xylol and toluol, after beginning neutropenia, hyperleukocytosis dropped;

with xylol, monocytes 40% (absolute count 13,000); with toluol, monocytes 30% (absolute count 5,000). Von Oettingen, Neal, and Donahue,⁴ in their work on the toxicity and potential dangers of toluene, showed no such changes in the blood picture. Greenburg, Mayers, Heimann, and Moskowitz,⁵ in a study of 106 painters exposed to the inhalation of toluene of between 100 and 1,100 parts per million for periods of time ranging from two weeks to more than five years, found that such exposure produced moderately decreased levels of erythrocytes, increase in absolute lymphocyte counts, but such exposure did not result in leukopenia. They found the best evidence of early chronic toluene intoxication in man to be enlargement of the liver, and macrocytosis. Woronow noted a very marked shift over to myelocytes and found basically stained granules in the neutrophils and their predecessors.

While Duke⁶ considered the blood platelets as the most sensitive element in these instances of isolated thrombocytopenia, Orzechowski believed that the blood platelets remained normal. As a rule, according to Brücken,⁷ and Bock and Wiede,⁸ the blood platelets are severely affected. All the investigators note an extraordinary hyperemia of the bone marrow, which becomes deep red, as a result of overfilling of the venous sinuses and the presence of very few cellular elements except a few mesenchyme cells, monocytes, lymphocytes, and plasma cells.

Differential Characteristics of the Anemias

Table 58 was developed at the Gradwohl School of Laboratory Technique to aid in teaching the laboratory findings in some of the anemias. It is not intended to be a complete review of the various anemic conditions, but simply a handy reference.

Pseudoanemia (Sahli)

Pseudoanemia of Sahli has been called by the Germans "Schein" or "apparent" anemia. It is a form of anemia well described by Baar and Stransky.⁹ Affected children appear pale but there is no diminution in the amount of hemoglobin in their blood. The blood has a normal composition. The face is pale, the visible mucosae are pale and the ear lobes when viewed through transmitted light are pale. This condition is frequently seen in school children. These children are known as "poor eaters" complaining of weakness, malaise, cold hands and feet. Mueller¹⁰ has divided these cases into three groups:

1. Neuropathic children with disturbances in their vagi and sympathetic nervous system. This leads to a contraction of the peripheral small cutaneous vessels, with consequent pallor of face.

TABLE 58.—CHART OF THE DIFFERENCES

	BEGINNING PERNICIOUS ANEMIA	ADVANCED PERNICIOUS ANEMIA	PERNICIOUS ANEMIA UNDER TREATMENT	CHLOROSIS (IRON DEFICIENCY ANEMIA)	APLASTIC ANEMIA
Erythrocyte count	Slightly low- ered	May be as low as 1,500,000 or lower	Let it go above normal as a rule in treat- ment	Around 4,000, 000 (except in very severe cases)	Progressively erasing red cou
Hemoglobin	Slightly low- ered	Drops quite low but not as much proportionately as drop in red count	Rises under treatment	Very low 50- 60%	Progressively ered. About s rate as red co.
M.C.V.* cu. μ	Slightly over 94	100 or higher	80 to 94	Less than 80	80 to 94
Blood vol- ume	Low	Below normal	Below normal	Very low	Very low
M.C.H.C.† %	Slightly above 30	Slightly above 30	Greater than 30	Less than 30	Less than 30
Leukocyte count	Slightly lower, if any change	Leukopenia (3000-4000)	Rises back to normal	Usually higher, around 10,000	Progressively lowered
Differential	Very little sig- nificant change. Any change will be shift to the right	Leukopenia, neu- tropenia, right shift, hyperseg- mented neutro- philes, lymphocy- tosis, monocytosis. In very serious cases may see myelocytes	Gradual return to normal	Lymphopenia; frequently a "stab" shift	Normal at beg- ning without young cells. 1 small lympho- cytes up to 10 Never any im- ature white cell
Reticulo- cytes	Increase. Go higher after liver treat- ment	Depends upon the amount of regen- eration in patient	Begin to rise on 4-5th day and continues to rise until 10th day. Drops to normal	Increased	Usually have no at all
Blood plate- lets	Begin to de- crease	Low absolute	Begin to rise	Normal	May completely disappear
Red cells in spread	Polychromasia. Tendency of erythrocytes to enlarge	Anisocytosis with macrocytes. Poikilocytosis. Polychromasia. Basophilic punc- tation, hyper- chromia, macro- cytes and megalo- cytes, nucleated red cells; may find Howell-Jolly bodies, Cabot rings, marginal granules, erythro- cytes, etc.	Return to nor- mal. Increase in polychro- masia. Disap- pearance of pathologic erythrocytic findings, as a good sign	Very marked hypochromia. Poikilocytosis, anisocytosis, many micro- cytes, diffuse basophilia; normoblasts and micro- blasts may at times be present	Normocytic Normochromic No change in rocytes noted
Size of red cells	Majority are normal. Tendency to enlarge	Large	Return to nor- mal	Small	Normal
Pigment content of red cells	Not signifi- cantly changed	Hyperchromic (Increased)	Return to nor- mal	Decreased	Normal

*Mean corpuscular volume.

†Mean corpuscular hemoglobin concentration.

ly low	Normal	Normal	Indefinite	Hyperchro- mic (in- creased)

TABLE 58.—CHART OF THE DIFFERENTIAL

	BEGINNING PERNICIOUS ANEMIA	ADVANCED PERNICIOUS ANEMIA	PERNICIOUS ANEMIA UNDER TREATMENT	CHLOROSIS (IRON DEFICIENCY ANEMIA)	APLASTIC ANEMIA
Special ex- aminations needed	Blood volume and volume index. Reticu- locyte count, blood platelet count, van den Bergh, bone marrow punc- ture, gastric analysis	Reticulocyte count. Routine complete blood examina- tion. Same as beginning per- nicious anemia	Reticulocyte counts repeat- edly. Repeated red cell counts and hemo- globin	Complete blood picture	Bone marrow punc- ture. Routine hematology serially
Bone mar- row	Increase in megaloblasts	Great increase in megaloblasts. Decrease in granulocytes	Return to nor- mal, first show- ing increase in normoblasts	Not needed for diagnosis	Either absence of nucleated reds or great decrease. Only an occasion- al normoblast. May be fatty de- generation or in- filtration of sma- ll lymphocytes. Granulocytes dis- appear. May be plasma cells
Classifica- tion	Normocytic normochromic with macro- cytes	Macrocytic normo- chromic	Return to nor- mocytic nor- mochromic	Microcytic hy- pochromic	Normocytic normochromic
Important points in diagnosis	Increase in size of red cells. Increase in reticulocytes. Response of patient to treatment with erythro- cyte matura- tion factor (liver, vita- min B ₁₂)	Very low red count and hemoglobin and high color index. Low white count, right shift and hypersegmen- tation of neutro- phils. Megalo- cytes and megalo- blasts, hyper- chromia; increase in reticulocytes following liver therapy; low blood platelets	Reticulocyte re- sponse to liver treatment. Re- turn of blood picture to nor- mal	Tiny red cells with decreased pigment con- tent. Low col- or index	Entire blood and bone marrow pic- tures taken seria- ly, giving pictur- e of true aplasia

2. Abnormal distribution or disproportion between blood supply in various parts of the body; that is, a pallor not due to cutaneous vessel contractions but rather to diseases of the internal organs whereby a greater volume than normal remains in these organs.

3. "Local" cases; that is, pallor is due to apparent change in the transparency of the skin, a poorly developed capillary vessel network in the skin

Aron³ explains the first group on the basis of a poorly developed circulatory system; that is, a relative insufficiency of the heart. He claims that these cases show an abnormally low Livi Index (Index ponderabilis) which obtained by mathematical computation—

$$\sqrt[3]{\frac{\text{Body weight} \times 100}{\text{Body length}}}$$

Polycythemia (Erythrocytoses)

Polycythemia vera was described by Vaquez¹ in 1892 and Osler² in 1903. It is also called "erythremia." There is an enormous increase in the number of erythrocytes, abnormal distention of the blood vessels—or plethora—an enlargement of the spleen. There are hyperactivity of the myeloid tissue and the appearance of many young forms of erythrocytes. There is, as a result of this abnormal disproportion of cells and plasma, instead of 56 per cent of plasma, only about 10 to 20 per cent. These patients show a characteristic reddish complexion, due to the distention of the peripheral vessels of the face. The visible mucosae and the throat mucosa appear a dense purplish red instead of the pale red of an inflammatory condition. The face, hands, and feet feel abnormally warm. By reason of the distention, the capillaries in the face become widened and through local stasis, a cyanosis is apt to occur. In addition to these symptoms, there is an albuminuria and nephropathy. A few casts are found. The blood pressure is elevated. There is likely to be dilatation of the heart, weakness of the heart muscles and hydrops.

Subjective symptoms are headache, dizziness, vomiting, dyspnea, and sleepiness. Occasionally abdominal pains, especially in the left hypochondrium, are noted.

Hirschfeld and Stern call attention to the lowered temperature. Psychic and nervous symptoms are seen.

Polycythemia vera is generally considered a primary disease of the hematopoietic system of unknown etiology. There is evidence of increased activity of the bone marrow, as can be deduced from presence of immature cells in the peripheral blood and the occurrence of polychromasia, normoblasts, and myelocytes in the peripheral blood.

Studies have shown that the stomachs of man, dogs, swine, and cattle contain a substance which is a powerful stimulant of marrow activity in pernicious anemia. It is dialyzable through collodion and withstands esterification, properties that would seem to remove it from the enzymes. It is probably a hormone, for which the name "addisin" has been proposed. Pernicious anemia seems to be due to a lack of secretion of addisin. Theoretically, erythremia may be due to hypersecretion of addisin or hypersusceptibility of the bone marrow to it. This theory was advanced by Morris.³ In a patient with erythremia, having 8.9 million red cells, addisin derived from 1,250 c.c. of the gastric contents of swine was injected intramuscularly. On the fifth day following the injection, the reticulocytes, 1 per cent in amount, rose to 2.5 per cent. On the ninth day after the injection, a differential count showed 1 per cent myelocytes. This result indicated a response of the bone marrow to stimulation by addisin.

Examination of the sources of hematopoietic substances effective in pernicious anemia shows a high purine content (liver, kidney, stomach, nucleic acid).

¹Vaquez, L. H.: *Bull. med. Par.* 6: 849, 1892.

²Osler, Wm.: *Am. J. M. Sc.* 126: 187, 1903.

³Morris, Roger S.: *J. A. M. A.* 101: 200, 1933.

If pernicious anemia represents anaddisinism and erythremia represents hyperaddisinism, it would be theoretically possible to control erythremia by dietary measures. For this reason, Morris proposed a low purine diet continued over a long period of time for the treatment of erythremia.

Relative polycythemia* occurs when, through loss of blood plasma, the concentration of the red corpuscles becomes greater than normal in the circulating blood. **Transient polycythemia** occurs when in response to some stimulus red corpuscles are shunted into the circulation from some storehouse such as the spleen. **Absolute polycythemia** means an increase which is associated with an increase in the total red cell mass.

Absolute polycythemia may be divided into two forms, erythremia and erythrocytosis. Erythrocytosis thus denotes a polycythemia which occurs in response to some known stimulus, whereas erythremia refers to a disease of unknown etiology.

Relative polycythemia may be caused by dehydration and may give the patient the appearance of an absolute polycythemia. In this condition, however, there is a diminished blood volume but no real overproduction of red blood cells. This occurs following excessive exercise in which there has been an unusual excretion of water through the skin and lungs. Prolonged vomiting, diarrhea, and fever may be causative factors. In other words, it is due to loss of water from the blood plasma following abnormally lowered fluid intake or marked loss of body fluids. The differential diagnosis depends upon the presence of increased red blood cells associated with diminished blood plasma volume as determined by the hematocrit. The condition is usually transitory, definite improvement occurring by dilution of the blood with fluids.

Transient polycythemia occurs when contractions of the spleen throw red blood corpuscles into the circulation in response to such stimuli as exercise, anoxemia (low oxygen tension, hemorrhage, suffocation, carbon monoxide poisoning), certain drugs, emotional conditions which produce an increase in the excretion of adrenaline into the circulating blood.

Erythrocytosis is analogous to erythremia except for the fact that it is secondary to a known cause and, as generally conceded, usually represents an effort on the part of the organism to compensate for difficulties in the oxygenation of the blood or tissues of the body, the underlying cause of the increased blood production being oxygen want. First, there may be a defective saturation of arterial blood with oxygen as evidenced by the erythrocytosis of high altitude (mountain sickness). This occurs not only in people who live in high altitudes but in travelers as well who go up in planes or climb mountains. Blood counts may reach 7.5 or 8 million cells per cu.mm. This condition from a similar cause (that is, poor oxygenation) is also found in the newborn, congenital heart disease, certain forms of acquired heart disease and pulmonary diseases, and in those conditions due to a defect in the hemoglobin of the blood so that it is unable to combine with oxygen in normal amount as manifested by the toxic action of various bacterial and chemical poisons on the red blood cells.

*This section to the bottom of page 774 is an excerpt of an article by Meyer, H. M.: Lab. Digest 5: 4, 1941.

Under these conditions red cell counts as high as 13.9 million have been recorded, hemoglobin as high as 23.7 gm. (normal, 13.0 to 17.3 gm.), while the volume of packed red cells averages 54.4 c.c. per 100 c.c. (normal, 41.9 c.c. to 42.9 c.c.).

Erythremia or **polycythemia vera** is a slowly and intermittently progressive disease of unknown etiology characterized by a striking absolute increase in the number of red blood corpuscles, and in the total blood volume, and frequently by signs of generally increased bone marrow activity.

Attention was called to this disease in 1892 by Vaquez, some time following the development of a method for counting red blood corpuscles in the middle of the nineteenth century.

The disease is more common in males than females; a fair percentage of the cases are found in Jews born in Eastern Europe. It usually occurs in middle or late life. Several persons of the same family may be affected. The majority of workers in this field believe that the pathologic physiology is an increased activity of the blood building apparatus.

Patients are usually vague in their statements concerning the date of onset of their symptoms. From histories of slight discomfort or vague ill-defined complaints it is evident that the disease is likely to have been present for a long time before it finally obtruded itself upon the consciousness of the patient. Individuals may apply to their physician for cosmetic reasons, to be rid of the unnatural red flush of the skin, and may be otherwise symptom free. Such general symptoms as weakness, lassitude, easy fatiguability, loss of weight, and shortness of breath are frequently present. Various gastrointestinal symptoms including abdominal pain, eructations of gas, anorexia, nausea and vomiting may occur. Skin and mucous membrane hemorrhages are not uncommon. Nervous symptoms manifested by headache, dizziness, noises in the ears, tingling sensations of hands and feet, staggering gait, muscular weakness, blurring of vision, thickness of speech, and even loss of consciousness may be complained of.

On physical examination one finds the characteristic reddish-blue color of the skin and mucous membrane, or there may be a definite pallor. The spleen is enlarged in the majority of cases; the size of the spleen varies greatly at different periods of the disease. Enlargement of the liver occurs in more than 50 per cent of the cases. Blood pressure is usually within normal limits. Muscular twitchings or paralysis may be present. There is no enlargement of the heart in the majority of the cases. Palpitation is complained of by many patients. The disease may be latent for years. After it has become fully manifest, its course is chronic, slowly progressive, and ultimately fatal. Patients may live over a period of from four to twenty years or more after the onset of the recognized symptoms. Death usually results from vascular complications, especially cerebral thrombosis or hemorrhages. Serious and often fatal hemorrhages have occurred from esophageal varices, the stomach, lungs, and other viscera. Heart failure may be the terminal event.

Examination of the blood reveals a marked increase in the red cell count. It usually ranges from 7 to 12 million per cu.mm., the highest authentic count recorded being 13,600,000 per cu.mm. It has been calculated theoretically that with red cells of normal size the circulatory system would be unable to con-

tain the blood if the count exceeded 13,900,000 per cu.mm. The blood is characteristically dark and spreads slowly under the cover glass. It may be so thick that it is drawn up in a pipette with difficulty. Patients with 80.0 c.c. of packed red cells per 100 c.c. of blood have been observed.

In polycythemia the red corpuscles are often normal in size, but it is not uncommon to find that their mean volume is less than normal. Thus the average size in 14 cases was 83 cu. microns—the smallest cells being about 61 cu. microns.

The hemoglobin is also increased, but less than the red cells, so that the color index is ordinarily below 1, the usual range being 0.7 to 0.9. Hemoglobin values as high as 240% have been recorded; this would be equivalent to possibly 40 gm. of hemoglobin per 100 c.c. of blood, but it is more than likely that the hemoglobin determination in this case was not accurate. Hemoglobin values varying from 120 to 160%, or 18 to 24 gm., are common.

The blood counts vary appreciably from day to day; spontaneous remissions and relapses occur. Simultaneous blood counts from venous and arterial blood show in general no marked differences.

The red corpuscles as examined in the blood spread may appear quite normal; however, it is not unusual to find somewhat greater variation in size than is normal, and more rarely, poikilocytosis. Microcytes are not infrequent; macrocytes are unusual. Especially when the disease has become more advanced and particularly when hemorrhage has occurred, the red corpuscles appear paler than normal. Polychromatophilia, and less frequently basophilic stippling, may be encountered. Nucleated red corpuscles are not rare, but other indices of increased erythropoiesis are almost never encountered. Anisocytosis, poikilocytosis, polychromatophilia, and normoblastosis may be quite marked. Special staining reveals frequently a slightly increased reticulocyte count, often about 1 to 2 per cent. Great increases in reticulocytes are found only following hemorrhages.

Leukocytosis is quite common, the count varying from 10,000 to 25,000, but values up to 50,000 per cu.mm. are by no means rare. The leukocytosis is due to an absolute increase in the number of granulocytes. The cells of the myeloid series compose 70 to 95% of the leukocytes. Metamyelocytes are found in increased number, and it is not unusual to find 1 to 2% myelocytes; myeloblasts have also been observed. The eosinophilic and basophilic leukocytes may be increased, although this is less common. Lymphocytes are relatively reduced but usually their absolute number is about normal. Monocytes may be absolutely increased.

The blood platelets are usually increased; counts of 1,000,000 per cu.mm. are quite usual, and in some cases the count may exceed 3,000,000. Megakaryocytes are rarely found in the circulating blood.

Bleeding time is usually essentially normal, and coagulation time is normal. Clot retraction may be slow. The fragility of the red cells may be normal but is frequently increased. In dilutions of their own or normal serum, patient's cells might yield an abnormally long resistance span. Normal cells, however, may be hemolyzed in dilutions of patient's serum.

The viscosity of the blood in polycythemia is much greater than that of normal blood. It may be five to eight times greater. This is primarily due to

the great excess of red blood cells over plasma. The viscosity of the serum, indeed, is said to be less than is normally found in health. Likewise the specific gravity of erythremic blood is 1.075 to 1.080 as compared with 1.055 to 1.065 for normal blood. The sedimentation rate of polycythemic blood is very greatly delayed.

The total volume of blood in erythremia as measured by both the dye and carbon monoxide methods is found to be greatly augmented. Volumes of 121 to 246 c.c. per kg. of body weight have been found as compared to a normal value of 87 c.c. Plasma volumes are increased little or not at all. There is an increase in the blood in the organs in general, and even the smaller vessels of the pia mater of the brain and cord are engorged and distended with blood.

Sternal bone marrow puncture reveals a dark red marrow crowded with enormous numbers of mature erythrocytes as well as normoblasts. All the nucleated red corpuscles are small and contain round, ripe, and often pyknotic nuclei. Megaloblasts are frequently few or absent. Polychromatophilic red cells are few. The leukopoietic apparatus is also overactive with myelocytes and metamyelocytes predominating; even the promyelocytes may be increased in number. Mature neutrophils are reduced in number. Megakaryocytes may or may not be increased.

It has been found that whereas in normal persons glycolysis (that is, the digestion of sugar, or its utilization within the living organism) in blood containing not more than 100 mg. of dextrose per 100 c.c. is completed in about six hours, in the blood of patients with polycythemia the process was from two to three times as rapid, being completed in from one to four hours. Otherwise, blood chemistry shows no striking changes. Basal metabolism is elevated.

The important points in the laboratory diagnosis of polycythemia vera (the finding of a high red corpuscle count with high hemoglobin, and the finding of signs of increased bone marrow activity, polychromatophilia, nucleated red corpuscles, increased number of reticulocytes, leukocytosis with increase in the younger cells of the myeloid series, such as myelocytes and metamyelocytes, increase in the numbers of eosinophilic or basophilic leukocytes, thrombocytosis) justifiably arouse the suspicion of erythremia. Bone marrow examination may be of assistance.

Both the color index and volume index are low. The leukocytosis alluded to is around 15,000 to 16,000. There is a definite shift to the left, neutrophils forming about 75 per cent of the total differential picture.

The Treatment of Polycythemia

William Dameshek¹ gave a very excellent summary of the present concept concerning the treatment of polycythemia.

The treatment of polycythemia has passed through several successive stages since Osler first used benzol to reduce the excessive blood cell formation. Phenylhydrazine, a hemolytic poison, was introduced by Morawitz following its experimental use by J. H. Pratt. Although this new drug achieved wide popularity, its unpredictable nature and the severe hemolytic crises which often ensued made its use relatively hazardous. In some instances transfusions actu-

¹Dameshek, William: *Blood* 1: 256, 1946.

ally became necessary—a rather embarrassing situation. Other deleterious effects were on the circulation, the kidneys, and the liver. What is more, all the elements, including iron for enhancing further red cell formation, were retained within the body. For these reasons, the systematic use of multiple venesections to reduce the red cell mass and blood volume and induce a state of iron deficiency seemed far more physiologic. In Dameshek's experience, the removal of 500 c.c. of blood twice weekly for two to five weeks, depending upon the initial hematocrit and hemoglobin levels, has proved a satisfactory method. To maintain somewhat longer the resulting state of iron deficiency, it has been his practice to keep the patient on a diet low in iron. Red cell formation under these circumstances is only partially reduced, but hemoglobin and hematocrit levels remain low for periods of six to eighteen months, during which time the patient may be completely asymptomatic. Red cell levels during this induced remission gradually rise, so that the red cell count as an index of therapy is of little value. The best index is the hematocrit value, although the hemoglobin concentration alone may be used since this correlates fairly closely with the hematocrit level. With this method of therapy, patients go along for many years with very little more difficulty than do others in the older age group in which polycythemia occurs.

The use of x-ray therapy has, in Dameshek's hands, proved ineffective, either by heavy dosage to localized areas or by spray or generalized therapy. He has hesitated to use high voltage x-ray in these essentially normal individuals because of the possible dangers of radiation malignancy or leukemia. The introduction of radioactive phosphorus, as discussed by Erf,¹ makes therapy a good deal easier and is ordinarily productive of an excellent remission.

The treatment of patients with polycythemia vera with radioactive phosphorus (P^{32}) has become a well-established therapeutic approach. Lawrence and associates² report the nature and treatment of polycythemia vera in 263 patients. This series constitutes one of the largest groups studied for the longest time with radioactive phosphorus. These observers reflect the opinion generally held that irradiation therapy by this method is as safe, as simple, and as effective as any other known form of therapy. In our experience, radioactive phosphorus has been the treatment of choice, but in selected cases, such as those with considerably enlarged spleens, we have preferred radiation of the spleen by deep x-ray therapy. Isotope therapy has several advantages over deep x-ray therapy; namely, ease of administration, long remissions with single doses, absence of radiation sickness.

Thrombocytopenia of sufficient degree to cause bleeding may be an annoying complication but it not very frequent with standard dosages. In our experience, the hematologic effects of radiation, whether it be deep x-ray or isotope, are essentially the same. When radiation therapy is effective, the red blood cell count and hemoglobin diminish. As these values approach normal, symptoms generally improve.

We have used phlebotomy in patients with red blood cell counts over 6,500,000 per cu.mm. early in the program of therapy with isotope, since the effect of the therapy may not be evident before 3 to 6 weeks. The neces-

¹Erf, L. A.: *Blood* 1: 202-208, 1946.

²Lawrence, J. H., Berlin, N. I., and Huff, R. L.: *Medicine* 32: 323, 1953.

sity for further treatment has been based on the levels of the blood counts and symptoms. There does not appear to be any arbitrary level at which therapy is indicated. Block and co-workers¹ have treated some symptomatic patients with polycythemia vera with radioactive phosphorus even though their red cell counts have not been elevated. They have selected these cases on the basis of an extreme panhyperplasia and the absence of stainable iron in the bone marrow as seen in sections.

Other forms of therapy in polycythemia have been the use of nitrogen mustards by some. We feel that there are no apparent advantages of such therapy over irradiation, and there are obvious disadvantages, such as administration and toxic reactions.

There has always been and there still is a good deal of discussion concerning the relationship of polycythemia vera and leukemia or leukemoid states. The incidence of such relationships has always been very high and is generally considered a part of the natural history of polycythemia vera. There has been some understandable concern about the relationship of radiation therapy and such "complications" as leukemia. To date no strong evidence has been offered in this respect as related to the isotope therapy of polycythemia.

Symptomatic Polycythemia

In symptomatic polycythemia the relationship between red cell volume and plasma volume remains normal. There is no splenic tumor. The following forms of polycythemia have been described:

1. Concentration of the blood through abnormal perspiration or loss of fluid, such as we see in ulcer of the pylorus with frequent vomiting, in carcinoma of the esophagus, cholera, and trichinosis.
2. In cardiac and pulmonary diseases such as pneumothorax, apoplexy, emphysema, asthma, and bronchitis.
3. Toxic polycythemia due to carbon monoxide poisoning and acidosis.
4. So-called polycythemia hypertonica with atherosclerosis, hypertonia, and nephritis.
5. Splenic tuberculosis.
6. Splenomegalia.
7. Polycythemia of the newborn.
8. Compensatory polycythemia—seen in compensation in anemias and chlorosis, also in leukemias under roentgen ray treatment.
9. Hormone or internal secretory polycythemia.

Polycythemia hypertonica listed above has come under some scrutiny in the recent hematologic literature. Dameshek² apparently is speaking of this form of polycythemia under the title of "stress erythrocytosis." These individuals are usually men of the plethoric, obese, aggressive type with elevation of blood pressure. Acrocyanosis of the hands and feet may be pres-

¹Block, M., Bethard, W., and Jacobson, L. O.: Proc. Centra. Soc. Clin. Invest. 27: 16. 1954.

²Dameshek, W.: Blood 8: 282, 1953.

ent. Other than an elevation of the red blood count and hematocrit, all hematologic data are normal. Arterial oxygen saturation is normal, bone marrow studies are normal, and the red blood cell volume is normal. Plasma volume, however, is low. Lawrence and Berlin² emphasize the low plasma volume and suggest that it may be the result of long-continued psychic stress. These patients have such disturbances as peptic ulcers, coronary disease, and hypertension, a triad familiarly associated with psychosomatic disturbances. Dameshek stresses recognition of this group, chiefly to avoid the type of vigorous therapy traditionally given patients with polycythemia vera.

Polycythemia From High Elevations.—Bert³ described an increased hemoglobin in persons in the Andes from elevation of 4,400 meters. In the Himalayas, count of 8,300,000 has been described at an elevation of 6,000 meters. The natives of Tibet at an elevation of 4,866 meters show a red cell count of 7,600,000. At mountainous heights, the increase begins suddenly, becoming as high as 6,000,000 to 8,000,000 in twenty-four hours and reaching a definite height eight to fourteen days later. On returning to lower altitudes, the red cell count declines rapidly.

The cause of this elevation polycythemia has not been definitely determined. Some have claimed that it is due to the unequal distribution of red cells in the skin and in organs; others maintain that it is a vasomotor change. Meissen and his followers believe that it is a true increase in formation of red cells through lowered oxygen pressure.

AFFECTIONS OF THE WHITE CELLS

An increased number of leukocytes is called *leukocytosis*; a decreased number, *leukopenia*.

Leukocytosis

Variations may occur in the blood of the same individual even in health from day to day, or at different hours of the same day. These variations may be due to an increase in any one of the elements, that is, granulocytes, lymphocytes, or monocytes. In other words, there may be a granulocytic leukocytosis, lymphocytic leukocytosis, or monocytic leukocytosis. When there is damage to the tissue, the leukocytes mobilize from the blood to the site of injury and a discharge of these cells from the blood organs gives a general increase in the circulating blood. The purpose of the differential count is to tell what type of leukocytosis is at hand, whether of the granulocytic, lymphocytic, or monocytic variety. As a rule leukocytosis is usually granulocytic or neutrophilic. When we speak of neutrophilia we mean a neutrophilic leukocytosis. Neutrophilic leukocytosis occurs most frequently in acute infections, such as staphylococcus, streptococcus, etc. A similar leukocytosis occurs in pneumonia, whooping cough, scarlet fever, and some of the other infectious fevers.

Some authorities have spoken of digestive leukocytosis, that is, an increase in leukocytes during digestion, but this seems to be a misconception. There

seems to be a variation in the total white cell count during the day, usually a maximum of 9,000 to 10,000 in the afternoon and 5,000 to 8,000 in the morning. These variations occur quite independently of meals. Leukocytosis has been noted in pregnancy and during menstruation, and also as a result of muscular exercise or as a result of adrenal administration.

An increase in the number of eosinophiles, or eosinophilic leukocytosis, occurs in general in allergic states as in certain skin diseases, asthma, anaphylactic shock, and in infestations with animal parasites, such as the hookworm and the *Trichinella spiralis*. We have seen as many as 90 per cent eosinophiles in this latter condition accompanied by a marked increase in the total number of white cells.

In a general sense, the increase in the total number of leukocytes constitutes a normal protective reaction on the part of the blood. In disease, however, such as in leukemia, associated with increased number of leukocytes, this increase is a primary feature and not a reaction of defense in any sense. Leukemia is primarily a disease with a marked increase in the maturation and multiplication of white cells with appearance of abnormal forms due to factors at present unknown.

Explanation of the "Shift" of Schilling

It is generally believed that the following order of cell development occurs in the myelocytic series: First, the myeloblast of Naegeli; next, the promyelocyte of Pappenheim; third, the myelocyte of Ehrlich; fourth, the juvenile of Schilling; fifth, the "stab" or band form of Schilling; sixth, the segmented cell. The last three are what were formerly termed the polymorphonuclear cells. We must assume that the bone marrow forms erythrocytes and granulocytes; that it is "irritable" or responsive or highly sensitive to an acute degree to chemotactic, humoral and vegetative-nervous insults; that it is the primary carrier of cellular defensive forces against toxic substances in the body, especially proteogenous antigens. It was Arneth who first called attention to the left shift of neutrophilic leukocytes as a very important development of histologic changes in connection with clinical diagnosis and prognosis. All the credit must be given to him for calling attention to these nuclear changes. His work, however, is not, strictly speaking, a practical procedure, nor do the other types of cells which he has described in his book (*Qualitative Blutlehre*) conform to the original idea of a shift of the neutrophiles. The total scheme comprises an observation of more than eighty cell species. His theory embodies a shift to the left of only juvenile cells. The Schilling count divides cells as follows: basophiles, eosinophiles, myelocytes, juveniles, "stabs" or rods, segments, lymphocytes, and monocytes. The normal quantities are: basophiles, 0-1; eosinophiles, 2-4; myelocytes, 0; juveniles, 0-1; "stabs," 3-5; segments, 58-66; lymphocytes, 21-30; monocytes, 4-8. The neutrophiles are myelocytes, juveniles, "stabs," and segments, or a total of 67. He has proved that in the presence of infection there is a definite change in the proportion of these cells. In the beginning, due to the toxic impression upon the bone marrow, there is an interruption in the development from "stabs" to segments, with a consequent increase in "stabs."

PLATE XX.

To set forth the cells according to the Schilling method, construct a so-called hemogram as follows:

TOTAL NEUTROPHILES

	BASO- PHILE	EOSINO- PHILE	MYELO- CYTE	JUVE- NILE	STAB	SEGMENT- ED	LYMPHO- CYTE	MONO- CYTE
Normal %	(0-1)	(2-4)	(0)	(0-1)	(3-5)	(58-66)	(21-30)	(4-8)

Now draw a double line between the segments and the "stabs." If the neutrophilic cells to the left of this line increase, we call it a left shift. If the neutrophilic cells to the right increase, together with a decrease or absence of these cells on the left of the line, it is called a right shift. The true "right shift" shows numerous hypersegmented (6 or more lobes) neutrophiles.

A simple "degenerative blood picture" is a simple left shift in which the "stabs" increase in number. With a continued infection and with the defensive forces of the body acting intensively, under infection, this shift continues perhaps with the "stabs" remaining stationary, or increasing, but with the appearance of juvenile cells in the peripheral blood. At this time the appearance of juvenile cells indicates an irritation of bone marrow with regeneration. This is called a "regenerative blood picture." If the infection continues and the patient's resistance declines, the shift advances farther to the left. If improvement ensues, the shift declines and recedes to the right. A "leukemoid" shift is a shift in which the blood picture resembles leukemia; that is, a marked increase in myelocytes, juveniles, stabs, and segmented neutrophilic cells. In this type of shift, there are no eosinophiles or basophiles, and the number of lymphocytes and monocytes is very low; sometimes there are none. This is a serious blood picture.

Attention is also to be called to the change in number of the lymphocytes and monocytes during this infectious period. With a beginning shift to the left there is a coincident decline in lymphocytes. This decline continues until recuperation begins. With recuperation and retrogression of the shift toward the right, the lymphocytes increase. Manifestly a decline in lymphocytes indicates beginning infection, and increase in lymphocytes indicates resistance against infection. The neutrophilic regenerative shift implies a "battle" phase. Decline in lymphocytes indicates that the fortunes of war are with the invading organism; but with receding neutrophilia, a rising number of lymphocytes means a "phase of cure." At some stage in the infectious period when resistance overcomes invasion, the monocytes show a sudden rise. This occurs often even before the shift is materially changed to the right, and is what we term the "phase of defense." In the beginning of infections the eosinophiles decline and often totally disappear and reappear only when the shift turns about from left to right. This is termed "the dawn of convalescence." There is found, therefore, as a favorable prognosis, a return of eosinophiles, a shift changing from left to the right of neutrophiles, an increase in lymphocytes, and a marked increase in monocytes.

In chronic infectious conditions, a persistent high shift with low counts of eosinophiles and high counts of monocytes shows a chronic simultaneous

continuance of a phase of neutrophilic struggle and of monocytic defense. Thus the Schilling hemogram presents a kaleidoscopic view of infection in the blood picture which far surpasses in clinical import what we have

Fig. 196.—Tuberculosis, blood film, showing increase in "stabs" and segmented cells. ($\times 950$.)

Fig. 197.—Acute infection, blood film, showing increase in juveniles and "stabs." ($\times 950$.)

been accustomed to see with the old Ehrlich differential count. We are enabled to note infection, to note susceptibility, and to note resistance. We are also able to note, very clearly, an increase in the severity of the infection and can predict, with certainty, impending death. It is in impending death

that we see the "flooding" or liberation picture where the bone marrow has finally been overcome and the peripheral blood shows almost intact cells ordinarily found only in the bone marrow.

Broadly speaking, the Schilling hemogram shows a biological reaction to disease, but not necessarily a specific picture for each infection. It is true that there are certain conditions of infection which give rather specific blood pictures, but it does not necessarily follow that a diagnosis of a specific infection can be made entirely by the blood picture. Certain conclusions can be drawn very accurately in many infections from the blood picture; for instance, in pneumonia, which is characterized by a hyperleukocytosis and a neutrophilia with regenerative shift. The blood findings in tuberculosis are highly interesting. With activity, there is a marked shift with decline in lymphocytes; with resistance, a recession of neutrophils to the right, and a marked increase in lymphocytes.

In typhoid fever there is a very interesting degenerative left shift and leukopenia. Particularly interesting is the aneosinophilia in typhoid fever. In typhus, on the contrary, we find what Schilling is pleased to term the "gay blood picture," which shows marked increase in stabs, quite a few juveniles, in other words, a regenerative blood picture, together with irritation forms and plasma cells, and an increase in monocytes. This "gay blood picture" is also seen in measles and German measles, but is less marked. It is to be noted that monocytes with increased white count are conspicuous in variola, but less marked in varicella, scarlet fever, and mumps.

It goes without saying that the Schiller differential count presupposes a knowledge of the exact appearance of the different types of blood cells. It is exceedingly important to recognize the difference between a juvenile, a "stab," and a segmented neutrophile. It is equally important not to confuse the lymphocytes with the monocytes. We have found that the work can best be done by the use of the Giemsa stain, and by rigidly adhering to the Schilling technic in general.

The **nuclear shift index** (Schilling) is used particularly when the number of neutrophils in the hemogram is low. The exclusive use of the index obscures the interpretation. The nuclear shift index is the relation of pathologic neutrophils (myelocytes + juveniles + "stabs") to segmented forms. Normally the index is 4:64, or 1:16.

Thus in a blood picture with no myelocytes, no juveniles, 2 "stabs," and only 18 segmented forms, the shift index is 1:9, which is a left shift.

Absolute Counts of Leukocytes

Absolute counts of each type of leukocyte are seldom made, but at times they are very valuable to determine whether there is overactivity or underactivity of certain hematopoietic systems where the differential count alone does not show this clearly. To obtain the absolute count of each type of white cell, multiply the patient's white count by the per cent of each cell as represented in the differential count.

Normally the average white count is 7,500 leukocytes. The normal differential count of Schilling is

Baso- philes 0-1	Eosino- philes 2-4	Myelo- cytes 0	Juveniles 0-1	Stabs 3-5	Segments 58-66	Lympho- cytes 21-30	Mono- cytes 4-8
------------------------	--------------------------	----------------------	------------------	--------------	-------------------	---------------------------	-----------------------

The absolute count in a normal individual, roughly, would be

Baso- philes 0 to 75	Eosino- philes 150 to 300	Myelo- cytes 0	Juveniles 0 to 75	Stabs 225 to 375	Segments 4,350 to 4,950	Lympho- cytes 1,575 to 2,250	Mono- cytes 300 to 600
----------------------------------	---------------------------------------	----------------------	----------------------------	---------------------------	----------------------------------	--	------------------------------------

In the following case the absolute counts are given below the differential count.

White Count 2,400	Baso- philes —	Eosino- philes —	Myelo- cytes —	Juve- niles —	Stabs —	Seg- ments 35	Lympho- cytes 60	Mono- cytes 5
Absolute Count	—	—	—	—	—	840	1,440	120

At first glance it appears from the differential that there has been alteration in function of the lymphopoietic system which resulted in an increase of lymphocytes. From the absolute count this is clearly seen as only a relative change. The absolute number is slightly below the normal limits.

In pertussis, there is an absolute lymphocytosis. A leukocyte count of 25,000 or more with a great increase in lymphocytes manifestly shows involvement of the lymphocytic system; the white count increase is therefore due to increased production of lymphocytes

SPECIAL INTERPRETATION OF THE HEMOGRAM

(A) In Acute Infections.—

1. All blood pictures with beginning regenerative shifts and moderately high white counts are considered more favorable than those with degenerative shifts; nevertheless, rapidly increasing or very marked regenerative changes must be cautiously interpreted, especially if the white count decreases.
2. Marked signs of degeneration with decreasing white counts indicate a continuation of the infection.
3. Hyperregenerative and atypical hyperplastic blood pictures are serious symptoms that demand rapid removal of the cause, otherwise irreparable damage to hematopoiesis takes place and death will follow.
4. Constant aregenerative or aplastic blood pictures with low white counts are serious symptoms.
5. Approximately normal blood pictures and percentages must be seriously interpreted until sufficient time has elapsed to convince the *experienced* observer that the probable impending grave condition will not develop. The type of the hemogram, DETERMINED BY EXPERIENCE, must always form the basis of a general estimation in any given case.
6. Marked decrease of eosinophiles accompanied by rising leukocytosis, indicates an *aggravated* condition.
7. Total disappearance of eosinophiles (aneosinophilia*) with simultaneous marked lymphocytopenia is to be regarded as an *unfavorable* condition.
8. Constant presence of eosinophiles, especially if it parallels hyperleukocytoses, means a *favorable* situation.

*No eosinophiles in the thick drop.

9. Reappearance of eosinophiles (after absence from the thick drop) or increase in eosinophiles, with receding neutrophilia, with transition from lymphocytopenia to lymphocytosis, means a *very favorable* condition.
10. Moderately high white count, moderate differential change, without or with slight shift, and with eosinophiles, means a *favorable* condition.
11. The same picture in chronic conditions as an indication of a torpid cure shows a *doubtful* result.
12. Moderate or high white count with marked left shift, few eosinophiles, and slight decline in lymphocytes, indicates a condition not yet to be regarded as unfavorable.
13. Very high white count with marked left shift, with very young cells and marked neutrophilia, decrease of lymphocytes, and aneosinophilia, suggests a *doubtful* or *unfavorable* condition, especially if these findings become more pronounced.
14. Decreasing low white count, or leukopenia, with very high neutrophilia and beginning shift to the left, lymphocytopenia, and aneosinophilia, indicates a fatal prognosis.
15. Varying high white counts with constant hyperregenerative "leukemoid" or even irregular blood pictures mean a *very unfavorable* outcome.
16. Subnormal white counts with degenerative shift of neutrophiles, lymphocytosis, monocytosis, and presence of eosinophiles *per se* are *not unfavorable*.
17. Very low white counts with severe degenerative shift, neutropenia, and aneosinophilia, with only relative lymphocytosis and monocytosis, indicate an *unfavorable* state.
18. The retrogression of an existing shift (regenerative or degenerative) and of the neutrophilia or neutropenia, with approach to the normal count, with reappearance of the eosinophiles, is to be regarded as *always* favorable.
19. On the contrary, a blood picture showing a marked left shift deviating extensively from the normal count and accompanied by a decrease in or total disappearance of eosinophiles is *unfavorable*, and the more extensive the deviation from the normal, the more unfavorable the picture.
20. Marked decrease of lymphocytes in infections where there have been hyperleukocytoses of long duration shows a *complication*.
21. Sudden decrease of lymphocytes with increasing neutrophilia and shift, often with recurrent decreasing total white count ("fall of lymphocytes") is a *very serious condition*.
22. Parallelism between lymphocytosis and hyperleukocytosis is a *favorable symptom*.
23. Transition from neutrophilia to neutropenia, with receding shift, with increasing lymphocytosis, and eosinophilia is a *very favorable condition*.
24. Numerous younger or irritation lymphocytes with normal or abnormal white counts indicate active processes.
25. In acute infections with hyperleukocytoses, monocytosis is regarded as a *favorable symptom, receding only in more severe affections*.
26. In chronic infections, monocytosis indicates activity.

(B) In Anemias.—

1. Considerable polychromasia, or normoblasts without degenerative elements in the film, with increasing red count and color index near 1.0, indicates a *favorable* condition.
2. Very marked regeneration (numerous normoblasts and erythroblasts, considerable polychromasia) and a low red count is to be considered a *doubtful* picture.
3. A low red count, decreasing hemoglobin, and decreasing color index, without much polychromasia, with signs of degeneration (basophilic stippling, isolated normoblasts, nuclear debris, special forms), means an *unfavorable* picture.
4. A low red count, leukopenia, lymphocytosis, megalocytosis, and color index above 1.0 (megalocytic or pernicious anemia blood picture), means an *unfavorable* picture.
5. Constant low red and white counts without regeneration, followed by degeneration or aplasia, is distinctly a *very unfavorable* condition.

Problematic Hemograms in Infections

Blood pictures given below represent the type of picture expected in these diseases at the height of the infection. Manifestly complications occur, which will, of course, alter the blood picture. (See pages 791 ff. for specific hemograms.)

Scarlet Fever.—

Leukocytosis, neutrophilia, regenerative shift, slight eosinophilia, atypical lymphocytes and monocytes, plasma cells, Doehle's inclusion bodies. (The "gay" blood picture.)

Purulent Meningitis.—

Leukocytosis, neutrophilia, regenerative shift, hypoeosinophilia, lymphopenia.

Tuberculous Meningitis.—

Slight leukocytosis, eosinophilia, left shift (indefinite), neutrophilia, lymphopenia.

Pyelitis, Empyema, Puerperal Sepsis, General Septic Complications.—

Neutrophilia, usually leukocytosis (leukopenia if fatal), regenerative shift, lymphopenia, and eosinopenia or aneosinophilia; monocytes depend on the resistance of the individual.

Influenza, Dengue, etc.—

Leukopenia, slight stab shift, lymphocytosis, neutropenia, monocytosis.

Local Peritonitis.—

Moderately high white count, slight neutrophilia, slight shift, lymphopenia or normal lymphocyte count.

General Peritonitis.—

High leukocytosis, regenerative shift, neutrophilia, lymphopenia, eosinopenia or aneosinophilia.

Grippe, Uncomplicated.—

Leukopenia, neutropenia, slight stab shift (10%), lymphocytosis, monocytosis, presence of eosinophiles.

Grippe, Complicated with Pneumonia.—

Leukopenia becomes leukocytosis, degenerative shift becomes regenerative, lymphocytosis becomes lymphopenia, neutropenia becomes neutrophilia, and eosinophiles decline in number or disappear entirely.

Severe Mastoiditis.—

Leukocytosis, neutrophilia, regenerative shift, lymphopenia, eosinopenia. This condition sometimes shows only a stab shift if resistance is very low.

Measles.—

Leukopenia, regenerative shift, neutrophilia, lymphopenia, plasma cells (the "gay" blood picture).

Pertussis.—

Leukocytosis, lymphocytosis as high as 80%, neutropenia, left shift index.

General Infections.—

Leukocytosis (or leukopenia, if very unfavorable), neutrophilia, regenerative shift, lymphopenia, and hypoeosinophilia or aneosinophilia; monocytes depend on the resistance.

Polyarthritis Acuta.—

Leukocytosis, neutrophilia, right shift, or no shift, lymphopenia.

Erysipelas.—

Leukocytosis, neutrophilia, regenerative shift. Eosinophiles, monocytes, and lymphocytes depend on the resistance of the patient, although there is usually lymphopenia, and hypoeosinophilia or aneosinophilia.

Lobar Pneumonia and Senile Pneumonia.—

Leukocytosis, high grade regenerative shift, neutrophilia, lymphopenia, hypoeosinophilia or aneosinophilia, plasma cells.

Typhoid Fever, Uncomplicated.—

Leukopenia, neutropenia, degenerative shift (marked), aneosinophilia or hypoeosinophilia, lymphocytosis, and monocytosis.

Typhoid Fever with Septic Complications.—

Leukocytosis, regenerative shift, neutrophilia, lymphocytopenia, and absence or decrease of eosinophiles.

Typhus.—

Leukocytosis, neutrophilia, high-grade regenerative shift, atypical lymphocytes and monocytes, plasma cells (the "gay" blood picture).

Diphtheria.—

Leukocytosis, neutrophilia, regenerative shift, lymphopenia, eosinopenia or aneosinophilia.

Parotitis Epidemica.—

Neutropenia, leukopenia, lymphocytosis, eosinophilia, marked degenerative shift.

Rocky Mountain Spotted Fever.—

Leukopenia, or normal white count, neutropenia, unknown shift, monocytosis and lymphocytosis, with a marked anemia and the presence of marginal corpuscles.

Variola.—

Neutrophilia, regenerative shift, leukocytosis, plasma cells, the "gay" blood picture, lymphopenia.

Varicella.—

Neutropenia, leukopenia, unknown shift.

Poliomyelitis.—

Leukopenia, neutropenia, unknown shift.

Osteomyelitis.—

Hyperleukocytosis, neutrophilia, regenerative shift, hypoeosinophilia or aneosinophilia, lymphopenia.

Severe Streptococcus Infection, General.—

Marked leukocytosis (or leukopenia, as a serious finding), high neutrophilia, marked regenerative shift, lymphopenia, eosinopenia or aneosinophilia.

LEUKOPENIA

Leukopenia is a reduction in the number of leukocytes in the circulating blood below 4,500 per cu.mm. The leukopenic state has been reproduced experimentally and occurs clinically quite frequently. It has been the subject of much investigation.

Lawrence¹ lists five possibilities as playing a role in the pathogenesis of leukopenia:

1. Diminished manufacture of white blood cells. This may be the result of (a) simple inhibition, (b) maturation arrest, (c) aplasia of the bone marrow, and (d) infiltration of the bone marrow with foreign cells.

2. Increased elimination of white blood cells. This may occur when large quantities of cells are poured into infected areas, such as an empyema, or when large numbers of cells are lost through normal channels such as the gastrointestinal tract, the lungs, the spleen, or the liver.

3. Increased rate of destruction in the peripheral blood due either to abnormal white blood cells or to abnormal substances in the blood channels, which cause destruction of the white blood cells.

4. Redistribution of the white blood cells in the vascular channels, such as occurs with foreign proteins.

5. Redistribution of the white blood cells in the body as a whole, as is seen at times in leukopenic phases of leukemia.

Although this summary of the causes of leukopenia is apparently all-inclusive, it is very difficult to fortify all these conditions with experimental or clinical facts.

It is thought that virus infections, typhoid fever, malaria, and overwhelming infections can be cited as examples of simple inhibition; nevertheless, there

¹Lawrence, J. S.: J. A. M. A. 110: 478, 1941.

is a possibility that other mechanisms enter into the causation of leukopenia in these conditions. Virus infections, such as influenza, dengue, viral hepatitis, viral pneumonia, acute poliomyelitis, vaccinia, are almost always accompanied by leukopenia. It is rather interesting that such a large number of virus infections is associated with a low white blood count, which is in sharp contrast with the leukocytosis which occurs in most bacterial infections. It might be worth while philosophizing that in viral infections, leukocytes are not a predominant defense mechanism, and are therefore not called upon to handle the infection. Typhoid and malaria (after the attack) are given as examples of simple inhibition, but it is rather interesting that both of these diseases are associated with splenomegaly, a condition which is associated with leukopenic states, perhaps due to some form of "hypersplenism."

Maturation arrest of cells of the myelocytic series is most frequently associated with agranulocytosis, due to drug intoxication, such as the sulfonamides. In these instances, some hypersensitivity phenomenon has been implicated as the *modus operandi* of the maturation arrest phenomenon.

Although leukopenia may be seen at times in aplasia of the bone marrow, it is rather surprising how infrequently this phenomenon is associated with rather marked aplasia of the bone marrow in various clinical conditions. Such aplasia may be due to idiopathic states or may result from therapy which destroys the bone marrow. Such therapy includes radiation, both in the form of x-ray and radioactive isotopes, and may be associated as well with severe nutritional deficiencies.

Infiltration of the bone marrow with tumor cells of various kinds includes metastatic carcinoma, multiple myeloma, and other diseases, but a simple explanation is not forthcoming for the leukopenia associated with such states. The relatively simple explanation of overcrowding by tumor cells is hardly acceptable. The author (H. A.) has observed numerous cases of widespread invasion of the bone marrow by carcinoma and in sections of these marrows has seen very active myelopoiesis alongside invading tumor.

When we speak of diminished manufacture of white blood cells within the bone marrow as a cause of leukopenia, we must also take into account the delivery of cells into the peripheral blood. This is a subject about which, at the present time, we know practically nothing. There are numerous examples of bone marrow overcrowded with white blood cells and with a peripheral leukopenia and vice versa.

Palmer and associates¹ have been able to reproduce in rats a disorder closely resembling the clinical syndrome in man to which the term "secondary hypersplenism" has been applied. This syndrome, produced by the injection of methyl cellulose in rats, presents a picture characterized by splenomegaly, hyperplasia of the bone marrow, and leukopenia, among other things. In their animals, if splenectomy were performed prior to the injection of the methyl cellulose, no leukopenia occurred; in fact, a splenectomy type of leukocytosis appeared; whereas in animals injected with methyl cellulose and developing the full syndrome, leukopenia was evident. They point out the

¹Palmer, J. G., Eichwald, E. J., Cartwright, G. E., and Wintrobe, M. M.: *Blood* 8: 72, 1952.

prophylactic role of the splenectomy in their animals, and also state that infiltration of the bone marrow by methyl cellulose-containing macrophages is not the explanation for the pathogenesis of these changes. They particularly point out that pancytopenia failed to develop in splenectomized animals, even though there was an equal degree of infiltration of the bone marrow by the methyl cellulose, and the bone marrows of the animals given the methyl cellulose were characterized by hyperplasia of the blood-forming tissue.

No discussion of the subject of leukopenia could be complete without invoking the present interest in immunologic processes as a cause of anemia, thrombopenia, and leukopenia. Well-documented experimental and clinical studies have been numerous in the literature concerning the role of immunologic abnormalities relating to the red blood cells, hemoglobin, and the platelets. However, fewer reports are present concerning leukocytes. Kissmeyer-Nielsen¹ carried out transfusion experiments to prove the presence of a leukopenic factor in the blood of patients with leukopenia, and he believed that he could demonstrate such relationship.

In speaking of the leukopenic phases of leukemia, most observers are referring mainly to granulopenia or neutropenia. In acute agranulocytosis, unquestionably the disappearance of the granulocytes is due to the failure of the myeloblasts or the myelocytes to mature into adult cells. It has been found that the bone marrow varies according to the stage of the disease, but at times myeloblasts may be the only representatives of the granulocytic series.

Only a few minutes are required to cause the disappearance of granulocytes from the blood after a small dose of amidopyrine in some patients. Vejens, in Norway, found that certain hydrophile colloids, like globulin, which produce leukopenia when injected intravenously, do so by causing the white cells to take up a marginal position in the venules of internal organs such as the liver, spleen, and omentum. This is really a type of "leukocytic shock" because the leukocytes are temporarily out of the circulation. This may be caused by gelatin, globulin, and fibrinogen.

Piney² called attention to chronic neutropenia which falls in the diminished manufacture group. Here the only clinical syndrome is apparently causeless fatigue or lassitude, with a granulopenia of less than 200 cells per cu.mm. In these cases, treatment, including pentnucleotide, fails to influence this neutropenia, although Piney's patient recovered after receiving Hepatex T.

With respect to the fifth possibility, redistribution in the body as a whole, the mechanism that is responsible for the distribution of the white blood cells between the tissues and the vascular channels is unknown. Lawrence gives as the best illustration of this the so-called aleukemic leukemia. In this condition there may be leukopenia and yet the various tissues in the body may be filled up with white blood cells. That this may occur in other conditions is a distinct possibility.

Many of the facts relating to the cause of leukopenia have yet to be developed.

¹Kissmeyer-Nielsen, F.: *Acta haemat.* 9: 337, 1953.

²Piney, A.: *Lancet* 1: 348, 1941.

BLOOD PICTURE IN VARIOUS INFECTIOUS DISEASES

Typhoid Fever

Typhoid fever is characterized by leukopenia down to 3,000 to 5,000 per cu.mm., and a left shift. Eosinophiles disappear at the beginning of typhoid fever. They do not reappear until the third week of the infection.

We may read from the hemogram certain definite prognostic facts in typhoid fever as follows:

1. A very few eosinophiles in the first stage speaks for a mild infection. The reappearance of the eosinophiles in the third stage of typhoid fever is a good prognostic factor. A relatively high neutrophile percentage is found in the prodromal stages; as the disease becomes more pronounced there is neutropenia plus lymphocytosis. A supervening neutrophilia is indicative of a possible complication, especially if there is a regenerative shift. A return of lymphocytes or a regression of the shift in the third stage is a favorable symptom.

2. Unfavorable symptoms are a continued leukopenia and an increasing left shift.

The mechanics of the lowered white count in typhoid fever is undoubtedly a toxic insufficiency of the bone marrow. See page 788. Studies of the bone marrow in this disease show very few myelocytes and many myeloblasts.

Typical typhoid fever counts are as follows:

White Cells 3,500. Slight polychromasia.

Bas.	Eos.	Myel.	Juv.	Stab		Segs.	Lymphs.	Monos.
0	0	0	0	18		39	35	8

White Cells 8,450. Red Cells 3,360,000. Hb. 65%. CI 0.9.

Bas.	Eos.	Myel.	Juv.	Stab		Segs.	Lymphs.	Monos.
0	0	0	4	48		15	33	0

White Cells 6,650.

Bas.	Eos.	Myel.	Juv.	Stab		Segs.	Lymphs.	Monos.
0	0	0	12	32		23	32	1

White Cells 11,800.

Bas.	Eos.	Myel.	Juv.	Stab		Segs.	Lymphs.	Monos.
0	0	2	7	43		23	24	1

Paratyphoid A and B Infections

Paratyphoid A and B cases show a reduction, possibly to one-half million, of red cells with a lowered hemoglobin content and therefore a lowered color index. The leukopenia is not as pronounced as it is in typhoid fever. The left shift is about the same.

Typhus

In typhus the hemogram is as follows:

Total white count 8,000.

Bas.	Eos.	Myel.	Juv.	Stab		Segs.	Lymphs.	Monos.
0	0	0	5	16		46	27	6

There are many plasma cells. Schilling calls this picture the "gay" or the "colorful" blood picture.

Naegeli is inclined to think of a slight leukocytosis in typhus. He cites seventeen cases by Slatineano with 14,000 leukocytes, and thirteen cases by Cazeneuve with from 10,000 to 30,000 leukocytes. Rothacker does not think that the leukocyte count is ever higher than 14,000.

The diagnostic symptoms in the blood picture of this disease are the "gay" blood picture with a left regenerative shift. Eosinophiles do not disappear quite as rapidly and uniformly as they do in typhoid fever. Cazeneuve places considerable diagnostic importance upon the appearance of myelocytes (2 to 12 per cent) in typhus.

Most authorities speak of a marked decline in the number of red cells in this disease, accompanied by a hemoglobin drop, sometimes down to 52 per cent. Dychno¹ describes red cell resistance figures up to 0.32 to 0.36 per cent.

Malaria

The general blood changes in malaria are as follows: anemia is always present. It is caused both by direct destruction of erythrocytes due to the development of the parasites within them and also by toxic influences. There is oligocytosis, a lowered hemoglobin content, and a lowered color index. Polychromasia is usually marked, and coarse basophilic punctation is a frequent blood finding. In cases with severe anemia normoblasts are found. There may be nuclear spheres, marginal granules, and other nonspecific indicators of anemia. Parasites have been observed in polychromatic and stippled erythrocytes, and even in normoblasts.

Malaria pigment may frequently be found in phagocytes, usually in large monocytes (pigmentophages), although we have seen them in all four types of neutrophilic cells. This pigment is yellow or brown, and light refracting. It is usually arranged in characteristic clumps. It originates from devoured or phagocytized parasites and is important in detecting malarial infection when no parasites are found. It is demonstrable not only in blood spreads, but also in thick drop preparations.

During the attack, there is irritation leukocytosis with marked regenerative shift, neutrophilia, and decrease in the number of eosinophiles. *During reduction of fever and shortly following this*, there is leukopenia, marked monocytosis and relative lymphocytosis, with slight eosinophilia. In severe relapsing cases there is a continuous "stab" shift. In *chronic cases*, low white counts, monocytosis and lymphocytosis are found. The white count rises rapidly, but only temporarily, shortly after an open or latent attack. In this condition parasites are scarce. If there is a continued shift with monocytosis after treatment, it is thought to indicate recurrence. In clinically suspected malaria where no parasites are found in the blood, one is led to the diagnosis of malaria if polychromasia is present as two or three plus in the thick drop, if basophilic punctation is found, and if lymphocytes and monocytes are markedly increased, especially if quinine has already been administered.

¹Dychno: *Ztschr. Hyg.* 101: 203, 1923. Quoted by Naegeli, L. C.

All varieties of malaria show similar blood pictures, but acute *falciparum* malaria may show a higher neutrophilia with a regenerative shift to myelocytes.

In parasite-negative cases, the administration of 0.5 to 1 c.c. of 1 per cent Adrenalin may aid in the demonstration of the parasites. Other methods that have been used are repeated ultraviolet ray exposures, severe physiotherapy with alternating hot and cold douches. Thick drop should be examined repeatedly at intervals of several hours.

In blackwater fever there is a marked decrease in the number of erythrocytes and in hemoglobin content. This is soon followed, with improvement, by a very marked regenerative normoblastic blood picture. Upon continuation or onset of new attacks, megaloblastic or aregenerative (reverse) blood pictures occur. This is an unfavorable symptom. Deaths have occurred in blackwater fever due to suppression of erythropoiesis. Parasites usually disappear temporarily during an attack of blackwater fever.

Falciparum Malaria

In tropical malaria, there may be both a hyperleukocytosis and a left shift. The typical hemogram of **falciparum malaria** is as follows:

Bas.	Eos.	Myel.	Juv.	Stabs		Seg.	Lymph.	Monos.
0	0	0	18	32		20	18	12

In the thick drop there are marked polychromasia and basophilic punctation and many ring forms of *Plasmodium falciparum*.

In this disease there is a severe hyperleukocytosis with a comparatively high lymphocytosis and an increase in monocytes. There are no eosinophiles and there is a marked toxic polychromasia.

Influenza

Influenza is characterized by a leukopenia with a left shift. A typical hemogram is as follows:

White Count 4,000.								
Bas.	Eos.	Myel.	Juv.	Stabs		Seg.	Lymph.	Monos.
0	0	0	0	15		58	23	4

Tuberculosis

Beginning tuberculosis shows an increased total white count and distinct left shift.

The erythrocyte sedimentation test, while not specific for tuberculosis, is useful in following the progress of the disease. With the Wintrobe tube, the following designations have been introduced by Doan, Wiseman, Mercer, and Miller.¹ Designate arbitrarily the normal rate as +. Deviations from the normal are designated ++, +++, or +++, depending upon the sedimentation velocity of the red blood cells as evidenced by the type of curve obtained during the first hour, a fall approaching the vertical being designated as +.

¹Doan, C. A., Wiseman, B. K., Mercer, S. T., and Miller, M. D.: Ohio S. M. J. 28: 333, 1932.

Severely ill patients all show a maximum fall in one hour. With general clinical improvement and regressive lesions the sedimentation rate returns to normal.

The red cells show a slight reduction in total numbers in tuberculosis, except in the terminal stages.

The count of the white blood cells is very important in tuberculosis. The discovery by Sabin, Doan, and Cunningham² of the relationship which exists between the monocyte of the circulating blood and the epithelioid cell of the tubercle forms the basis for the increased interest in the cellular mechanism of this disease. Cunningham, Sabin, et al.³ first showed the importance of the monocyte-lymphocyte ratio as obtained from differential counts of the circulating blood. Progressive tuberculous lesions showed a gradually increasing monocyte and a decreasing lymphocyte count, while regressing lesions were accompanied by a reversal of these relationships, that is, by a lowering of the monocyte-lymphocyte index in the blood (normal is 0.33). Qualitative changes in the monocytes, with the appearance of epithelioid cells in the peripheral blood, are quite as significant as the quantitative changes just mentioned. Medlar⁴ has emphasized the importance of the neutrophilic leukocytes in appraising the incipency and extent of caseation and cavitation in tuberculous foci. Wiseman⁵ re-evaluated certain qualitative changes in lymphocytes with reference to age and maturity, which when applied to the study of these cells in tuberculous cases further aids in the analysis and prognosis of the disease. Wiseman found the normal average lymphocyte formula to be 5 per cent young basophilic types, 45 per cent mature moderately basophilic forms, and 50 per cent old, faintly basophilic lymphocytes. In tuberculosis, the increase in young, immature forms denotes an additional strain placed on the lymphatic tissues. It has been recognized for a long time that resistance to tuberculosis is associated with a relative lymphocytosis, but it is essential that the lymphocytes be relatively mature to serve their function. Thus, in known tuberculosis patients, if the total lymphocyte count is relatively low, with a degenerative rather than a regenerative "shift to the left," the prognosis is grave, even though the monocytic-lymphocytic index may not be markedly increased.

In tuberculosis, there is a shift of the neutrophilic leukocytes with an increase in the "stabs." With increasing severity, there is a regenerative blood picture. The commonest type, however, is the degenerative picture. Progressive cases show a falling lymphocytosis. Cases doing well show normal lymphocytes, or an increase. Eosinophiles are usually present and their presence or absence is of little significance. The same is true of basophiles. Allusion has already been made to the ratios between the monocytes and lymphocytes.

⁴Medlar, E. M.: *Am. Rev. Tuberc.* 20: 312, 1929.

⁵Wiseman, B. K.: *J. Exper. Med.* 53: 499, 1931.

Bredeck⁶ in the study of fifty-nine cases of tuberculosis, with reference to the Schilling differential count, showed that all definitely active cases of pulmonary tuberculosis have a positive infectious blood picture. Three cases, in which a diagnosis of tuberculosis was made by other physicians some time ago, showed no evidence of tuberculosis except by x-ray, but these three had negative infectious blood pictures.

Bredeck instituted a method for utilizing the tuberculin test in connection with the Schilling blood count as a guide, with a diagnosis of tuberculosis established, in determining the progress of the disease. Tuberculin causes a specific focal reaction with characteristic blood changes. In short, it is the best agent for inducing focal activity. His method is to make a differential blood picture and then give an injection of tuberculin, 10 mg. After this injection, if the patient is tuberculous, there will be a characteristic change in the blood picture, decrease in the lymphocytes and a marked increase in the "stab" cells, and an increase in monocytes. Changes in the blood differential count after tuberculin occur before the fever reaction, and with smaller doses of tuberculin than those that induce fever. The Schilling count, together with the subcutaneous tuberculin test, constitutes the most delicate and most accurate methods in the diagnosis of early manifestations and induced focal activity. A shifting of the neutrophilic leukocytes to the left in the Schilling blood differential count is a constant finding in clinically active tuberculosis. An increase in lymphocytes indicates healing and a diminution indicates progression of the disease. High lymphocyte counts, with increase in monocytes and with little or no change in neutrophils, indicate healing. A drop in lymphocytes and an increase in monocytes, with an increase in the shifting to the left of the neutrophils, indicate active progression of the disease. The prognosis of tuberculosis depends upon the severity of the shifting of the neutrophils to the left and degree of changes in the number of lymphocytes. This, together with the Wiseman count of the lymphocytes, constitutes an admirable method for estimating the future of these tuberculosis cases.

Typical hemograms follow:

Bas.	Eos.	Myel.	Juv.	Stabs		Seg.	Lymph.	Monos.
0	1	0	0	6		54	27	12

Chronic tuberculosis with cavities shows:

White Count 10,000.

Bas.	Eos.	Myel.	Juv.	Stabs		Seg.	Lymph.	Monos.
0	2	0	0	9		46	34	9

A severe picture of active tuberculosis, with serious prognosis, follows:

White Count 20,000.

Bas.	Eos.	Myel.	Juv.	Stabs		Seg.	Lymph.	Monos.
0	1	0	0	20		51	19	9

Advanced tuberculosis, as follows:

White Count 22,000.

Bas.	Eos.	Myel.	Juv.	Stabs		Seg.	Lymph.	Monos.
0	0	0	7	38		17	14	24

Croupous Pneumonia

In croupous pneumonia there is a marked hyperleukocytosis, together with a very severe left shift. The total counts may exceed 35,000, especially in children, when it may be 50,000. This is a marked neutrophilic leukocytosis with a left shift. Occasionally myelocytes may be found during the height of the disease. The leukocytosis occurs very soon after the beginning chill and remains until the crisis occurs. With the crisis, there is a return of the eosinophiles and the appearance of monocytes—the so-called “dawn of convalescence.” One is accustomed to think of a severe hyperleukocytosis in croupous pneumonia as a favorable symptom and the absence of a leukocytosis as a very unfavorable symptom. If leukopenia is found in croupous pneumonia, the prognosis is very grave. There is very little change in the red cell picture in croupous pneumonia, and only a very small reduction in the erythrocytes and hemoglobin. Blood platelets are increased and the sedimentation rate is markedly heightened.

The following hemogram is from a man 25 years of age, with pulse 110, respiration to 40, temperature 104° on the fourth day of the disease.

White Count 12,575. Red Count 4,865,000.									
Bas.	Eos.	Myel.	Juv.	Stabs		Seg.	Lymph.	Monos.	
0	0	0	15	51		27½	10½	1	

Another interesting series of hemograms follows from a case of left-upper lobar pneumonia. Note that on November 21, the day of the first hemogram, the patient was at the height of his process, having a temperature of 104° F. The crisis occurred on November 25. At that time his temperature dropped to 99.4°, becoming absolutely normal on December 3. Note hemograms of November 25 and December 3.

Date	Total Leukocytes	Bas.	Eos.	Myel.	Juv.	Stabs	Seg.	Lymph.	Monos.
11-21-34	23,500	0	0	0	8	38	47	5	2
11-25-34	13,775	0	3	0	0	15	47	22	13

12-7-34	9,313	0	1	0	0	5	34	51	9

The effect of the administration of sulfathiazole on the blood picture in lobar pneumonia is well seen in the following case from our service at the Christian Hospital, St. Louis. Note the lowering of the leukocyte count, together with a more favorable shift of the neutrophils, and the return of the eosinophiles. Monocytes are increased, forecasting recovery.

The patient, a 58-year-old white woman, entered the hospital on Jan. 3, 1942. Several days before entry she became ill, with chills, coughing, and finally expectoration of rusty sputum, and pain in the left chest. There were no cardiac or gastrointestinal or genitourinary complaints. Patient was slightly undernourished, coughing, febrile, and looked very ill. Abdomen: soft; no tenderness or masses, or palpable viscera. Heart sounds were of good quality. Blood pressure: 115/70. Lungs: Bronchial breathing, increased fremitus, flatness of left lower lobe, with moist râles. Also moist râles and bronchovesicular breathing over spots in the right middle lobe and right base. Kidneys not tender, not palpable. Reflexes normal. Very slight edema of legs.

The sputum was of tenacious and rusty character. Pneumococci Type I were present. Pulse was 120; temperature, 103.6° F.; respiration, 24. Diagnosis: pneumonia. Sulfathiazole, 30 grains, was administered twice on the first day, then 15 grains every four hours there-

after. Oxygen was administered through nasal catheter. Treatment was continued throughout the second day. Patient seemed in a stupor. Pulse thready. Urinated involuntarily. Fingertips cyanotic.

The accompanying series of blood pictures was obtained. (Patient was discharged on the twenty-sixth day.)

The following case from our service at the Christian Hospital, St. Louis, Mo., is presented through the courtesy of Dr. H. A. Klein.

Patient, A. G., a well-developed male, entered the hospital on May 11, 1945, with history of chills and fever and chest pains. Râles in entire right lung. History of illness, two weeks. Left humerus broken; since then weak cough. Diagnosis: Lobar pneumonia, right, middle, and upper lobes.

Patient was dismissed on June 27, 1945.

Bronchopneumonia

The leukocytosis in bronchopneumonia is not nearly as high as it is in croupous pneumonia, seldom over 15,000. In bronchopneumonia due to influenza, as already stated, the picture is a leukopenia and there is a left shift.

Virus or Atypical Pneumonia

In contradistinction to bronchopneumonia, virus pneumonias have leukopenia with a left shift. However, there generally is present a moderate lymphocytosis. Owrens, Kelley, and Agress¹ showed that in some cases there may occur a very marked absolute and relative lymphocytosis associated with a leukocytosis up to 20,000. During this period, such cases may be confused with acute infectious mononucleosis. However, the pathologic lymphocytes of acute infectious mononucleosis either were absent or were present in only small numbers. The heterophile antibody test was negative.

Tularemia

The blood picture in tularemia is a neutrophilia with a left shift. Hemograms of two cases reported by the author² are as shown in Tables 60 and 61.

¹Owrens, M. H., Kelley, R. W., and Agress, H.: Med. Bull. North African Theatre of Operations 2: 56, 1944.

Bubonic Plague

There is a neutrophilic leukocytosis, around 40,000. Platelets are increased. There is a very marked left shift.

Leprosy

The predominant feature of the blood in leprosy is an anemia. Leukocytes are not increased, eosinophilia is not common.

Erysipelas

There is a hyperleukocytosis with a marked regenerative shift to the left. Total neutrophiles may attain a figure of 90.

Encephalitis Lethargica

This is characterized by a slight increase of leukocytes with a moderate degree of anemia. There is a slight left shift. Some have reported a leukopenia and also an eosinophilia during the convalescent period. The type of encephalitis that occurred in St. Louis in 1933 showed a slight leukocytosis and a left shift.

Coccidioidal Granuloma

There is a moderate leukocytosis, usually around 15,000. Eosinophiles are sometimes above normal. Riesman and Ahlfeldt¹ reported a case with 22,000 white cells and 12 per cent eosinophiles. There is a secondary anemia.

Blood Picture in Appendicitis*

The data following represent a composite study of 97 consecutive operative cases of appendicitis. This analysis was made during our service at the St. Louis County Hospital. In all cases a hemogram was made, the clinical history studied, the operative findings recorded, and the gross and microscopic pathology of the appendix thoroughly analyzed. The purpose of the study was to correlate, if possible, the entire picture—clinical, histologic, and pathologic—and to attempt to draw conclusions on what one might expect from the blood picture as to the type of appendix to be found at operation.

For purposes of study and analysis, we made an arbitrary division of these clinical pathologic entities into five groups, as follows:

Group I. Thirty-one in number, which we decided to name *acute* appendicitis.

Group II. Twenty-seven cases in all, which we called *ruptured* or *necrotic* appendices.

Group III. Thirty-one cases in all, which we called *chronic* appendicitis with a flare-up or an acute exacerbation leading to operation.

Group IV. Five cases in all, characterized by *no definite pathology* in the coats of the appendix, aside from pressure effect from fecal impaction.

Group V. Three cases in all, which we are constrained to say exhibited no acute pathology, either gross or microscopic, which could be classified appendix inflammation.

We have selected a typical case from each one of the five groups for purposes of description.

Case No. 35-588, Group I.—History: Entered with pain in the right side, nausea but no vomiting. **Examination:** Tenderness in both lower quadrants, most pronounced on right side, with muscle guard and tenderness. **Hemogram:** 14,500 white count; 11 stabs, 58 segments, 30 lymphocytes, 1 monocyte. **Operation:** Day of entrance. Appendix found injected, some old adhesions to right tube. **Gross Examination:** Appendix about 6 cm. long with thickened wall; injected. **Microscopic Examination:** Mucosa markedly deep and friable in section; lymphoid elements in submucosa very abundant; tremendous invasion of lymphocytes and neutrophils into middle coat; small blood vessels filled with organized clots. **Microscopic Diagnosis:** An acute appendix inflammation.

*This is an abstract of a monograph by the author, read before the Pan American Medical Congress, General Medical Section in Havana, Cuba, January, 1938.

¹Riesman, D., and Ahlfeldt, F. E.: *Am. J. M. Sc.* 174: 151, 1927.

Case No. 35-598, Group II.—History: Entered hospital with pain in the right lower quadrant and in epigastrium. Vomited everything taken by mouth. *Examination:* Reveals a very sick child of 10, undernourished, abdomen greatly distended throughout, particularly over the right lower side. *Hemogram:* 17,800 white cells; no eosinophiles; 45 stabs; 35 segments; 15 lymphocytes; 5 monocytes. *Operation:* Same day, showed peritoneum filled with pus and fecal smelling fluid. Small fecalite found with perforation present at midpoint. *Gross Examination:* Appendix about 6 cm. long, tip very distended and discolored. *Diagnosis:* Ruptured appendix and peritonitis. *Microscopic Examination:* Very thick walled appendix with a very scant layer of mucosa. Intense infiltration of lymphocytes throughout all coats. The tissue appears necrotic as noted from the poor staining qualities of the entire area. *Microscopic Diagnosis:* Ruptured necrotic appendix.

Case No. 35-611, Group III.—History: About 2 weeks before entrance, patient noticed definite pains in right lower quadrant at irregular intervals. Nauseated but not vomiting. *Examination* at hospital showed no palpable masses, slight rigidity of abdominal muscles, some rebound tenderness. Center of pain in right lower quadrant in a line along McBurney's point. General impression was of chronic appendicitis. *Hemogram:* White cells 16,950; 14 stabs; 58 segments; 25 lymphocytes; 3 monocytes. *Operation:* Day following admission. Appendix found to be imbedded posteriorly and retroperitoneally; by blunt dissection and cutting of adhesion the appendix was finally brought into view. *Diagnosis:* Chronic appendicitis. *Gross Examination:* A long thin appendix 9½ cm. long. *Microscopic Examination:* A small appendix in width, very narrow. Mucosa layer very thin. Penetration of "wandering" cells and erythrocytes. Peritoneal coat distinctly thickened and elevated showing a chronic organization. Blood vessels engorged in the peritoneal coat. *Microscopic Diagnosis:* Process is essentially a chronic change in outer coat and slight change in the middle layer.

Case No. 36-085, Group IV.—History: Patient has been sick for 24 hours with epigastric pain, later localized in right lower quadrant, followed by nausea and vomiting. Vomited all night and 3 or 5 times on day of operation. *Examination:* Showed right muscle guard; marked tenderness over McBurney's point and Meltzer sign positive; rebound tenderness. *Diagnosis:* Acute appendicitis. *Hemogram:* White count 10,250; 15 stabs; 67 segments; 18 lymphocytes; no monocytes. *Operation:* Appendix found to be closely bound down by a membrane which was dissected free. *Diagnosis:* Acute appendicitis. *Gross Examination:* Appendix 7 cm. long; thick walled; filled with fecaliths. *Microscopic Examination:* Fecal impaction in the appendix that showed very little change in the wall beyond some slight penetration of lymphocytes and neutrophils into the middle coat. Outer coat showed very little change.

Case No. 35-691, Group V.—History: Several months previous had history of sharp lancinating pain in the right lower quadrant prior to onset of menstruation. This patient became slightly nauseated but did not vomit. Pain remained rather constant until termination of menses. This experience was repeated in the following two months' menstrual periods. Patient became slightly more nauseated with each attack and of late has had backache and morning nausea. On no occasion has patient vomited with these attacks. *Examination:* No masses. Tenderness in both lower quadrants, especially right and over McBurney's point. No muscle guard or rigidity, no rebound pain. Right inguinal quadrant tender. Left inguinal quadrant negative. Impression: Chronic appendicitis, chronic salpingitis, ovarian cyst. *Hemogram:* 8,000 white blood cells; 1 eosinophile; 3 stabs; 62 segments; 30 lymphocytes; 4 monocytes. *Operation:* Showed some adhesions between appendix and the right adnexa. Right tubal wall thickened. *Gross Examination:* Appendix 7 cm. long. Thick walled. *Microscopic Examination:* Very thin wall; no changes in the submucosa lymphoid elements; narrow mucosa with few migrating or wandering cells in any of the layers. Muscular coat very thin. Peritoneal coat showed some very slight chronic changes in the shape of elevation with new elements of fibrous connective tissue beneath the outer layer. In general, this might be termed an atrophic appendix.

In order to make the findings more graphic, we confined the hemograms in this work to the following data: total white count, and number of stabs and segments comprising the total neutrophilia.

A study of the total count, differential count, and the febrile reactions, together with a knowledge of the clinical history, operative conditions, and pathology, permits one to draw certain very definite conclusions regarding inflammation of the appendix, diagnosis, and operability. It is evident that in all cases of disturbances of the appendix there is likely to be an increase in the white cells, together with a left shift. This left shift is likely to proceed farther to the left in cases of ruptured, gangrenous, and necrotic appendices than in any other type. In other words, the only differentiation which is possible from the blood picture between cases of the first group and those of the second group is possibly a more severe shift to the left. Certainly, the amount of the total count in the two types is not likely to be different. It is a fact, however, that in cases of ruptured appendices the total count begins to go down with an increase in the severity of the pathologic conditions of this variety; in other words, with probably decrease in resisting power of the organism.

Therefore the hemogram is of some assistance in elaborating the diagnosis of appendicitis; *one is in no way able to predict from the hemogram alone the exact degree of pathology which will be found at operation or after microscopic study.* Some clinical pathologists and surgeons attempt to draw conclusions of too refined a character from the hemogram in the presence of a disturbance in the right lower quadrant. We wish to emphasize that this study, together with other experiences, would cause us to hesitate to draw any conclusion other than the presence of inflammation of the appendix from any given hemogram. We do, however, acknowledge that a falling total count and an increased left shift is a prime indicator of a probable rupture with a severe peritonitis and possibly a fatal outcome. It can be noted that, first, there is an irregular fever in all types of appendix inflammation; second, there is a difference in the degree of symptomatology; third, there is very little difference in the height of the white count and in the left shift in most cases whether they belong to the acute group, so-called, or ruptured appendicitis, or chronic appendicitis with acute exacerbation. The distinction, if any, may possibly be a more pronounced left shift, but this is not a sufficient basis upon which to make an absolute differentiation. The blood picture in the chronic cases with intermittent flare-ups shows leukocytosis, together with a left shift, although this leukocytosis in a general way may not be as high as that commonly found in Group I or Group II. The obvious conclusion to be drawn from this investigation is that the surgeon must make up his mind as to the diagnosis from the clinical symptoms, the range of fever, and the blood picture; he must not attempt to prognosticate as to just what pathology he is likely to find from the blood picture alone. Attention, too, must be called to the fact that in the case of fecal impaction without much pathology in the appendix wall, the symptoms were mild but decisive, the blood count was increased in a total way, and there was a mild but definite left shift. In all probability, cases of this nature, if left alone,

would have resulted in an extension of the pathology to the wall of the appendix, possibly leading to rupture and peritonitis had they not been operated upon. A fecal impaction in the appendix must be regarded as a foreign body, which is a source of definite trouble and which may be a potential source of danger to the patient, a cause for removal.

Whether to operate or not and when to operate seem to be the much discussed points in surgical circles regarding inflammation of the appendix. If the pathologist is asked for his opinion on this question, he must unhesitatingly answer, from a study of these cases, that once a diagnosis is made, an operation should follow. There seems to be no criterion by which one may conclude that in a given acute case subsidence of the symptoms is likely to occur and an interval operation may be indicated. From the viewpoint of pathology, therefore, one must urge operation once a diagnosis has been established.

The three cases in women, in which the diagnosis was not substantiated by operation or pathology, were all cases of right-sided tubal difficulties. Possibly, in these cases, the use of the blood sedimentation test would have assisted in making a laboratory differentiation between inflammation of the appendix and right tubal difficulty. At this point, the value of blood sedimentation as one of the nonspecific methods of laboratory diagnosis must be emphasized.

Conclusions.—The use of the Schilling hemogram in appendix cases offers many advantages. It enables us to draw a very fine picture of the reaction of the organism to infection in the shape of a response of the bone marrow. The first effect of infection on the bone marrow is paralysis of the function, resulting in a temporary leukopenia. Continuance of the infection results in a stimulation with an outpouring of immature forms of neutrophiles into the circulation. Coincident with this is the disappearance of eosinophiles and a relative lowering of the lymphocyte count. Usually, too, there is a decrease in the number of monocytes. With improvement, eosinophiles reappear, monocytes attain a high level, and lymphocytes increase, together with a recession of the neutrophiles from the left to the right of the hemogram. Definite conclusions may be drawn by the laboratory worker concerning the reaction of the organism to the infection. All attempts, however, definitely to dictate the entire diagnosis and prognosis from the hematologic picture are to be discouraged. There should be an objective interpretation from the laboratory standpoint which is manifestly suggestive concerning the presence of infection and the degree of immune reaction. With no clinical data before him, this is as far as the hematologist should go. With the clinical data added to the hematologic picture, very definite conclusions may be drawn as to the reaction of the organism, the possibility of a serious infection, and the probability of recovery. The clinical facts and the hemogram enable us to form a prognostic picture. It is to be emphasized that the hematologist and the clinician must work hand in hand on the interpretation of the Schilling blood picture. If this is done, untold advantage accrues. If it is not done, there may be embarrassing moments when the hematologist presumes too much and draws conclusions from the blood picture alone. The conclusion is obvious from a study of the analysis of these cases that in appendicitis there are definitely a left shift and a leukocytosis.

The severity of this shift does not enable one to differentiate between an acute case and one that represents the flare-up of the so-called chronic or subacute case. The hematologic facts at once indicate that there is a definite pathology in the appendix. There is no method by which one may predict a subsidence of the infection, and the action of the so-called interval operation. In other words, with the left shift, the leukocytosis, and the clinical symptoms, diagnosis of the appendicitis ought to be determined immediately and the correct treatment ought to be instituted, namely, operative procedure. The ruptured cases, of course, show decreasing total counts and increasing left shifts. This has been the belief for many years. It has been amply confirmed in these cases.

The following hemograms represent typical findings in appendicitis (not part of the series of 97 just recorded).

Acute Appendicitis (Fatal—too late to operate).

White Count 27,800. Red Count 3,280,000. Hb. 60%.									
Bas.	Eos.	Myel.	Juv.	Stabs		Seg.	Lymph.	Monos.	
0	0	4½	19	51½		12	12½	½

Amebiasis

In amebic dysentery there is a secondary anemia and, in severe chronic processes, the erythrocyte count may drop to as low as 2,000,000, with a still greater reduction in hemoglobin. There is a hyperleukocytosis and a marked left shift. Eosinophilia is insisted upon by some and denied by others. It is a general belief of hematologists that the presence of eosinophilia indicates infestation with intestinal worms as a complication.

When amebic abscess of the liver supervenes, there is no special increase in leukocytes.

		Bas.	Eos.	Myel.	Juv.	Stabs		Seg.	Lymph.	Monos.

Second day	10,450	0	12	0	0	5		55	23	5

Allergic States

The majority of hematologists regard eosinophilia, together with a leukopenia, as a very marked sign of allergy (see Leukopenic index, page 1357).

Scarlet Fever (Scarlatina)

The so-called "gay" blood picture with increase of eosinophiles is characteristic of scarlet fever. Most cases show a marked neutrophilic leukocytosis. Values of 20,000 per cu.mm. in severe cases are often found. In milder cases, the count is around 10,000. The white cells are increased coincident with the exanthematous eruption. With decline in fever, the white cells gradually decline. In this disease, we find a persistent leukocytosis, sometimes for a long time after the decline of the fever. The count is usually back to normal at the time desquamation is finished.

Increase in the eosinophiles begins shortly after the onset. In the beginning of the disease, the increase is confined to the neutrophiles. The neutrophiles show changes in the nuclear structure with degeneration in the cytoplasm, with the formation of vacuoles, and basophilic clumping, the so-called Doehle inclusion bodies. (For further details see remarks on toxic granules on pages 648 and 650.) They are plump and usually heavily stained granules. Cocci are sometimes seen within the cells. Monocytes are numerous. There is a relative and absolute increase.

Roth claims that there is a sudden increase of neutrophiles in scarlet fever, and then a gradual rise to higher levels, with a postinfectious lymphocytosis, without increase of monocytes. Plasma cells are sometimes found, according to Ciuca,* and may be as high as 17 per cent.

The most interesting feature of the scarlatinal blood picture is the eosinophilia. In the first two days, the eosinophile count is low, increasing after the second or third day of exanthematous eruption. The following hemogram represents a case on the second day of the eruption:

Bas.	Eos.	Myel.	Juv.	Stabs	Seg.	Lymph.	Monos.
0	$\frac{1}{2}$	0	1	15	$57\frac{1}{2}$	$18\frac{1}{2}$	7

Plasma cells: $\frac{1}{2}\%$. 1 monocyte with lobulated nucleus.

The following hemograms are quoted from Naegeli:

Second Day. Total 16,680.

Bas.	Eos.	Neutrophiles	Lymph.	Mono.	Plasma Cells
0.1	2.3	83.9	5.2	8.1	0.4

Fourth Day. Total 15,520.

Bas.	Eos.	Neutrophiles	Lymph.	Mono.	Plasma Cells
0.4	5.3	68.0	17	8.5	0.9

According to Tuerk¹ scarlatina may show as many as 14 per cent eosinophiles. Naegeli found as many as 22 per cent. He has one record of 25 per cent in a leukocyte count of 10,000.

The maximum period for eosinophiles usually occurs at the end of the first week. In very severe and in lethal cases, the eosinophilia is absent, according to Ambrus,² Georgescu,³ Markovitch,⁴ and Ketschetkoff.⁵ Naegeli reports that on the third day of a case of severe septic scarlatina he found

*Ciuca: *Compt. r. Soc. de biol. Paris* 98: 1627, 1928.

¹Tuerk: *Monatschr. f. Kinderh.* 15: 1918.

²Ambrus: *Jahrb. f. Kinderh.* 101: 68, 1924.

³Georgescu: *Inaug. Dissert. Bukarest*, 1911.

⁴Markovitch: *Presse méd.*, 205, 1925.

⁵Ketschetkoff: *Zentralbl. path. Anat.*, 1892, No. 11.

only 0.5 per cent eosinophiles; on the fourth day the case ended fatally. Heubner and Roth⁶ also reported cases of septic scarlatina without eosinophilia.

The question has been raised—does the cause of the eosinophilia lie in the reaction of the skin in scarlatina? It is claimed that those cases which fail to show an eruption do not show eosinophilia. Schemensky⁷ observed one case of scarlet fever without an eruption and insisted that eosinophilia is due to the presence of some eosinophile-chemotactic substance in the skin which is increased in the period of exanthem. Basophilic cells also have been found increased in this disease sometimes as high as 4 per cent. A few myelocytes have been found, 3 per cent in a total count of 16,000 having been recorded.

There is always a severe secondary anemia in scarlatina. Occasionally nucleated reds have been observed.

The following hemograms were made from cases in the St. Louis Isolation Hospital, through the courtesy of the Superintendent, Dr. John Eschenbrenner:

Bas.	Eos.	Myel.	Juv.	Stabs		Seg.	Lymph.	Monos.
0	4	0	6	30.5		35	12.5	9.5

Lymphoblasts (?) 0.5 per cent, 1 normoblast, red cells show basophilic punctation and polychromasia 2+. 2% plasma cells.

Second day of eruption:

Bas.	Eos.	Myel.	Juv.	Stabs		Seg.	Lymph.	Monos.
0	3.5	0	0.5	10		38.5	40	7

0.5% plasma cells, basophilic punctation 2+.

From case four days after eruption began:

Bas.	Eos.	Myel.	Juv.	Stabs		Seg.	Lymph.	Monos.
0	4	0.5	1.5	17		42	19.5	11.5

4% plasma cells.

Hemogram of mixed infection scarlatina and measles, four days after onset:

Bas.	Eos.	Myel.	Juv.	Stabs		Seg.	Lymph.	Monos.
0	3.5	0	1.5	24.5		42	20.5	7.5

Plasma cells 0.5%, marked polychromasia.

Diphtheria and Scarlatina fifth day:

Bas.	Eos.	Myel.	Juv.	Stabs		Seg.	Lymph.	Monos.
0	3	0	0	12		62	12.5	9.5

1% plasma cells.

The following hemograms are also illustrative of scarlet fever:

Bas.	Eos.	Myel.	Juv.	Stabs		Seg.	Lymph.	Monos.
0	6	0	1	17½		47½	23	4½

Plasma cells ½%.

Ninth day.

Bas.	Eos.	Myel.	Juv.	Stabs		Seg.	Lymph.	Monos.
0	3	1	3½	17		35	28½	10½

Plasma cells 1½%.

⁶Heubner and Roth: Med. Klin. 1910.

⁷Schemensky: Zentralbl. f. inn. Med. No. 26, 1918.

Scarlet fever and measles.

Plasma cells $1\frac{1}{2}\%$.

Measles

In measles there are no characteristic changes in the hemoglobin content value or the count of the red cells. At the beginning of the disease there is a neutrophilic leukocytosis followed rapidly by neutrophilic leukopenia. The leukocytes appear during incubation, and the leukopenia is seen at the time of eruption. There is almost a continuous leukopenia, the lowest count recorded being 2,400, during the height of the disease. Usbeck found a leukopenia in the beginning inconstant. Hecker found an incubation period at the time of the appearance of the Koplik spots, a leukopenia as well as a relative and absolute lymphocytopenia with left shift and a decrease in eosinophiles. In the second half of the period of incubation, there is an increase in lymphocytes and a decrease in neutrophiles.

In the exanthematous period there is a leukopenia, absolute and relative decrease or absence of eosinophiles. This typical blood picture was found twelve times in forty-one cases examined. In recrudescence, there is a leukocytosis and a relative lymphocytosis and eosinophilia. There is not a left shift.

With complications, such as pneumonia, otitis, etc., we may find a leukocytosis, neutrophilia, and a left shift. The blood platelets at the beginning of the exanthematous period are decreased to 100,000.

During the eruption there is a marked left shift with predominance of young forms. There are plasma cells and the usual "gay" blood picture of Schilling. The following hemograms are typical of this disease:

W. H.

Bas.	Eos.	Myel.	Juv.	Stabs		Segs.	Lymphs.	Monos.
0	$10\frac{1}{2}$	0	0	5		20	52	7

Polychromasia and basophilic punctation. Plasma cells, $5\frac{1}{2}\%$.

G. H.

Bas.	Eos.	Myel.	Juv.	Stabs		Segs.	Lymphs.	Monos.
0	2	0	1	10		24	$51\frac{1}{2}$	7

Plasma cells, $4\frac{1}{2}\%$.

German Measles

The hemoglobin value and the red cell count are not characteristic. Leukocyte count is decreased or normal. The minimum count of the leukocytes is found on the third day after the eruption. The number of neutrophiles is absolutely or relatively decreased, while the lymphocytes and monocytes are increased. The eosinophiles and basophiles are unchanged. There is a characteristic "gay" blood picture, with numerous plasma cells.

Psittacosis

In psittacosis there is an absence of leukocytosis at the beginning of the infection. Leukopenia is present in a small number of cases. When the disease is at its height, there is a shift to the right of the neutrophils, accompanied by a distinct fall in lymphocytes. As the patient improves, normal distribution of the blood cells follows. There is a distinct acceleration of sedimentation time at the beginning of infection.

Varicella

There is no change in the hemoglobin and the red cells in this disease. Arneth found during the eruptive period of the disease in a 2-year-old boy a white count of 6,000, and with recovery, a restitution to normal figures. There is a left shift at the beginning, but this rapidly disappears. Nobecourt and Merklen reported fifteen cases, ages 1 to 5, without any characteristic changes.

In the suppurative stage, there is a characteristic left shift which decreases with the decline of suppuration. So far as the blood platelets are concerned, they decrease with the beginning of fever and increase with the decline of fever.

Variola

The blood picture of variola is characteristic and constitutes a very important link in the diagnostic chain. We find early in the disease a marked regenerative shift as follows (on the fourth day):

Bas.	Eos.	Myel.	Juv.	Stabs		Segs.	Lymphs.	Monos.
0	5	1	6.5	8		25	31	23.5

together with a marked hyperleukocytosis. We are also likely to find many plasma cells, 11 per cent plasma cells having been recorded. According to Schilling, there is a marked left shift and an increase in monocytes—not only the normal monocytes are increased but there are abnormal large juvenile forms of monocytes. Fischer has described myelocytes and large lymphocytic irritation forms in this disease.

Diphtheria

There is a characteristic leukocytosis in diphtheria. With the injection of diphtheria antitoxin, there is a rapid decline in the number of leukocytes. Schlessinger¹ investigated leukocytosis in experimental diphtheria in animals. After injection of diphtheria bacilli, he noted leukopenia together with a decrease in lymphocytes, and then came an increase in leukocytes. Heim² claims that leukocytosis runs parallel with the intensity of the infection. Others note an absolute and relative increase in neutrophils, together with a decline in lymphocytes in the beginning of the disease. Our own hemograms follow:

Eight days' duration—I. R.—

Bas.	Eos.	Myel.	Juv.	Stabs		Segs.	Lymphs.	Monos.
0	1	0	0	16		52	23	8

¹Schlessinger: Die Leukozytose bei Diphtherie, Arch. f. Kinderh. 19: 378, 1896.

²Heim: Arch. des mal. des enf. 48: 24, 1901.

Twenty-two days' duration—W. R.—

Bas.	Eos.	Myel.	Juv.	Stabs		Segs.	Lymphs.	Monos.
0	0	0	4½	15		56½	18½	5

Plasma cells ½%—marked polychromasia.

Pertussis

In pertussis, there is a leukocytosis, sometimes as high as 40,000 or higher. The younger the child, the more outstanding the leukocytosis. This leukocytosis is practically a lymphocytosis. In twenty-four cases in the catarrhal stage, there was an average of 20,000 white cells, of which 32 per cent were neutrophils and 66 per cent were lymphocytes. The highest leukocytic and lymphocytic figures are found during the paroxysm of the disease. Complications by streptococcus, pneumonia, or staphylococcus do not seem to influence the count. Thiemann found in a typical pertussis case, 42,000 leukocytes with 76 per cent lymphocytes and 19 per cent neutrophils.

There is a left shift of the neutrophils in either the catarrhal or paroxysmal stages. Count of the eosinophiles is not changed. Monocytes are normal at first but become slightly elevated later. In complications, there is likely to be a left shift in the neutrophils without any change in the lymphocytes.

Parotitis Epidemica

Lehndorf¹ reported the blood pictures of fourteen cases of mumps in adults. Leukocytes were normal. Lymphocytes were increased 30 to 65 per cent. Two per cent plasma cells were found. Neutrophils were decreased; likewise eosinophiles.

Wiese,² in 115 cases of mumps from the ages of 5 to 15, found the following (no changes in the hemoglobin and red cell count) :

Day of Disease	Bas. %	Eos. %	Myel. %	Juv. %	Stabs %	Segs. %	(Neutr.) %	Lymphs. %	Monos. %	Neutr.	Lymphs.	Total Leukocytes
1	—	—	—	—	—	—	—	—	—	—	—	—
2	1	5	—	2	9	21	32	47	15	1,760	2,585	5,500
3	2	5	—	1	6	14	21	59	13	1,144	3,216	5,450
4	1	3	—	—	1	11	12	68	10	0,972	5,508	8,100
5	1	12	—	1	4	17	22	57	8	1,771	4,589	8,050
6	—	6	—	1	1	27	29	55	10	2,088	3,960	7,200
7	1	7	—	2	2	36	40	48	4	4,080	4,896	10,200
10	—	—	—	—	—	—	—	—	—	—	—	11,600
11	1	7	—	2	2	40	45	44	3	4,896	6,820	13,000

There is a marked left shift and lymphocytosis together with a leukopenia in the beginning of the disease.

Septic Abortion

The following two cases show a very interesting condition. They are both cases of septic abortion; one terminated favorably and the other fatally. The one that terminated favorably had a very marked hyperleukocytosis and a marked left shift. The other, which terminated fatally, had leukopenia and a very marked left shift. The latter is always to be regarded as a very unfavorable condition; namely, a low white count and a marked left shift. This is found in severe infections preceding death and in cases of ruptured appendix with widespread peritonitis, which have a fatal ending.

Neutrophilia With Right Shift—Polyarthrititis Acuta

There is one condition in which one is likely to find a neutrophilia with right shift—polyarthrititis acuta. The following case reports from our service at the St. Louis County Hospital offer typical pictures of this condition:

W. D., aged 33, entered hospital with history of chills, fever, cough, and general malaise, diagnosed as influenza six weeks ago. Later had pain in lower back and left thigh on lying down, and left thigh began to flex on the abdomen. X-ray showed osteoarthritis involvement in the lower lumbar vertebrae, pelvis, and hip. Pelvis was markedly distorted. Diagnosed as hypertrophic osteoarthritis with pelvic distortion. Hemograms are submitted as follows:

C. D., aged 54, entered St. Louis County Hospital with history of painful swollen knee for one year; both feet swollen and painful for past six months. Heart enlarged, systolic murmur. X-ray report as follows: the right knee shows hypertrophic osteoarthritis with calcium deposits within the soft tissue and at the borders of the lower head of the femur. The tibial spines are accentuated. There is evidence of arteriosclerosis. The synovial structures are thickened about the right knee. The left knee shows similar pathology but to a lesser degree. The right ankle and foot show atrophy of bone with some erosion of the articular structures. Arteriosclerosis is also present. Diagnosis: Arthritic involvement of both knees and ankles, more marked on the right side.

Hemograms in this case showing leukocytosis, neutrophilia, and right shift are as follows:

Agranulocytosis

This disease has been called by various names. "Agranulocytosis" was the name given to the disease by Schultz,¹ who first described it. Schilling called the disease malignant neutropenia, which is a better designation than Schultz' term, which means literally a condition where there are no granulations in the neutrophilic cell. As a matter of fact, in this disease there is a marked diminution in the number of neutrophilic cells. It has also been called

¹Schultz, W.: Deutsche med. Wchnschr. 48: 1495, 1922.

angina agranulocytica, mucositis necroticans agranulocytica, agranulocytosis septicaemica simplex, stomatitis gangrenosis myelophthisica, malignant leukopenia, hypogranulocytosis, and sepsis with granulocytopenia. This condition was said by Türk to be a disappearance of the neutrophilic system.

Etiology.—It has been claimed to be largely due either to the influence of drugs or to a bacteriologic causative factor. It has been known to follow arsenical and bismuth injections. Madison and Squire² reported thirteen cases in which they thought this condition was due to the use of benzene chain derivatives. Watkins³ discussed the role played by barbiturates and amidopyrine in the causation of neutropenic states. Hardwick and Randall⁴ report a number of cases of parturition in which large doses of phenobarbital-sodium were given without once noting any development of neutropenia, although some have claimed that these drugs will cause malignant neutropenia. These writers did show, however, that a high degree of leukocytosis appears at the fifth hour post partum, which has, of course, nothing to do with the explanation of the etiology of agranulocytosis (see page 788).

Von Bonsdorff⁵ reported three cases with malignant neutropenia. In two cases it was virtually certain that medication with amidopyrine was the cause, and it was probably the cause in the third case. In some persons a few small doses of amidopyrine produce granulocytopenia, while in other cases it appears suddenly some time after large doses of the substance have been administered, without causing disturbance at the time of administration. This shows that therapeutic doses of amidopyrine in sensitive persons may have a detrimental effect on the general condition and on the hematopoietic organs. The action on the granulocytopoietic apparatus is stimulating as well as inhibiting. The total number of granulocytes decreases, but the immature and young forms increase. In some instances leukocytosis may follow. Amidopyrine influences the organs that produce the monocytes and lymphocytes as well as the erythrocytes. The changes disappear spontaneously when medication is discontinued. However, it may be assumed that the continuous use of amidopyrine may eventually cause grave clinical symptoms. Animal experiments proved likewise that the administration of amidopyrine or of related substances may eventually impair the hematopoietic organs and lead to leukocytosis, leukopenia, or anemia.

Kracke⁶ pointed out that coal tar products may be responsible for this disease. In one case he claimed that acetophenetidin was probably responsible for this disease. There have been attempts made to differentiate between the etiology of the acute cases and the so-called chronic cases. Roberts and Kracke⁷ were impressed by the increasing number of acute fulminant cases and the large number of so-called chronic cases. They claimed that the acute cases represent a very small percentage of the total number of individuals whose blood count is depressed to some degree. Kracke and Parker⁸ de-

scribed the effects of drugs containing the benzene ring on agranulocytosis. They state that a certain percentage of the cases are due to arsphenamine, a certain percentage to gold salts and perhaps other chemicals, leaving a large group of the idiopathic type with an unknown etiology. Since the disease is more prevalent among physicians and their relatives, nurses, and members of the allied professions than in any other group in the United States, it may be due to the ingestion of drugs which these professional persons are in the habit of using rather freely, that is, drugs of the benzamin group. In eleven cases investigated by Roberts and Kracke, various drugs were taken, such as amidopyrine and Empirin compound, phenacetine, acetanilid, amidopyrine, and Allonal. These cases did not include the chronic type. These investigators further studied the groups of people who are likely to use coal-tar drugs in a rather promiscuous manner, and they found in an investigation of nurses, students, physicians, etc., that 76 per cent ordinarily used a drug containing the benzamin group. It is their contention that in persons with a weakened, damaged, or idiosyncratic bone marrow, either acquired or congenital, the use of these drugs may produce the chronic form of malignant neutropenia.

It has been proved that drugs may affect the bone marrow in certain peculiarly sensitive individuals. For instance, purpura following quinine administration has been observed. Benzene administration may be followed by aplastic anemia. Krumbhaar noticed profound leukopenia and marked changes in the bone marrow from mustard gas poisoning. Dinitrophenol, a drug which was widely used for the treatment of obesity, has been followed by agranulocytosis. The amount of the drug and the period of time over which it is taken are unknown factors in relation to the development of this disease.

Infection is a factor that has been stoutly maintained by a number of observers. No specific organism has been shown to be consistently capable of producing agranulocytosis. Blood cultures in many cases have shown a variety of organisms. In some cases the culture is positive, in others, negative. *Streptococcus pyogenes*, *Escherichia coli*, streptothrix, pneumococcus, and others have been found in different cases.

Moeschlin and associates have shown the development of antibodies against white blood cells. Refer to section on Immunohematology for further information.

The disease begins usually with a sore throat of sudden onset. Occasionally, however, there is a history of long-continued sore throat. There is fever and prostration. It behooves the physician in all cases of sore throat to make a blood picture in order at least to eliminate the possibility of this disease. Examination of the blood will usually suffice to clinch the diagnosis, although often the hemoglobin and red count estimations are normal. Occasionally, there may be an unexplained severe anemia, but this is not common. The number of blood platelets may be normal or decreased. The white blood count is the most characteristic feature of the disease. There is a diminution of the total number, which may be down to 1,000 white cells. We have seen cases with counts as low as 500. The lower the total count, the fewer are the granular elements; so much so, that finally no granulocytes are seen at all

in the blood spread. The differential count shows a complete disappearance of neutrophilic leukocytes with relative lymphocytosis. Plasma cells and myeloblasts are occasionally found. The number of monocytes may be diminished. In fatal cases the number of white cells remains low and shows a progressive decline. Gradual increase in the percentage of neutrophiles and in the number of leukocytes is a favorable symptom. The nuclei of the neutrophilic segmented cells are blurred. The neutrophilic granules appear basophilic and coarse. These are the toxic granules first described by Cesaris-Demel. (See pages 648 and 650 for discussion of toxic granules.)

Blood Findings and Histories of Agranulocytosis Cases.—

Case 1.—A very interesting case of this disease in the author's service at the Christian Hospital is submitted through the courtesy of Dr. Melvin Staehle.

Admission complaints and findings: The patient, a 46-year-old woman, was admitted April 28, complaining of becoming acutely ill on April 24, with a chill, fever, severe sore throat, inability to swallow, headache, dizziness, and general malaise.

The appetite was poor, patient very constipated.

The abdomen was soft and distended. The liver and spleen were not enlarged. No tenderness or masses palpable. Heart sounds of fair quality; no murmurs.

Vesicular breathing; no definite dullness. A few moist râles, mostly at bases.

No renal tenderness, kidneys not palpable.

Reflexes physiologic.

Acute inflammation of the pharynx.

April 28, 1942.

Upon admission: Respiration 26. Temperature: 104°. Pulse 80.

Sulfathiazole was given.

April 29, 1942.

Sulfathiazole discontinued.

Pentnucleotide 10 c.c. 4 times daily ordered.

250 c.c. blood as transfusion. All blood taken. A severe reaction followed, with a chill, nausea. Lasted twenty minutes.

May 1, 1942.

Patient belonged to Group A₁. 250 c.c. blood, Group A₁, as transfusion; no reaction.

May 2, 1942.

250 c.c. blood, Group A₁, transfusion; no reaction.

May 3, 1942.

250 c.c. blood, Group A₁, transfusion. Discontinued, chill, headache.

May 5, 1942.

Pentnucleotide reduced to 2 times daily.

May 9, 1942.

Pentnucleotide discontinued, as the patient had been without fever for 4 days.

May 10, 1942.

Discharged from the hospital.

Case 2.—The following case history is from our service at Christian Hospital, St. Louis, Mo., and is presented with the permission of the attending physician, Dr. H. A. Klein. Patient, Mrs. S. K., was admitted to the hospital on Dec. 9, 1942, at 2:30 P.M. Complaint, sore throat of three days' duration; chills, fever, and general malaise. Family history, irrelevant. Personal history, usual childhood diseases; no other infectious diseases; no serious operations or injuries; has been housewife all of married life; no history of exposure to chemicals. History of present illness: Patient began having a "cold" five days before entry into hospital. Three days before entrance her throat began to feel sore, soon becoming so much so that she could not swallow. She has had some generalized aching pains, especially of the shoulder and hip joint, chills, fever, and sweating. The patient was told five weeks before entering the hospital that she had high blood pressure and was given amidopyrine gr. ii ss dosage, which she took for two weeks. She has also been given medicine for her "liver." Patient has not taken any sulfonamide drugs or headache powders.

Examination of the patient revealed the following. General condition: Well-nourished 65-year-old female patient who looks acutely ill in fair condition. Tongue coated; abdomen soft and distended; liver slightly enlarged; spleen not palpable; no tenderness or masses palpable; heart slightly enlarged especially on the left; no murmurs, sounds of fair quality, aortic sounds accentuated; pulse fast, regular, equal, well filled; blood pressure 150/120; vesicular breathing; no dullness, few moist râles; bases move; no renal tenderness; kidneys not palpable; nervous system: reflexes, questionable Babinski at right (voluntary?); pupils round, equal, react to light; acutely inflamed throat, necrotic spaces; extremities, no edema or injuries. Impression: agranulocytic angina.

Records of temperature, pulse, respiration, urinalysis, and blood picture on Dec. 9, 10, and 11 are:

Dec. 9. Leukocytes—2,800; erythrocytes—3,820,000; hemoglobin—78% Sahli; color index—1.0. Differential count:

	BAS.	EOS.	MYEL.	JUV.	STAB.	SEG.	LYMPH.	MONO.
	-	-	-	-	-	-	100	-
P.M.	Temperature			Pulse		Respiration		
3:00	102.6			122		22		
7:00	100.4			100		24		
9:45	106.0			160		40		
12:00	104.4			110		28		

Transfusion: 500 c.c. citrated blood.

Dec. 10. Leukocytes—1,800; erythrocytes—3,560,000; hemoglobin—68% Sahli; color index—0.9. Differential count:

BAS.	EOS.	MYEL.	JUV.	STAB.	SEG.	LYMPH.	MONO.	
-	-	-	-	-	2	98	-	(Only 50 cells were found on several slides)
A.M.	Temperature			Pulse		Respiration		
4:00	102.0			94		30		
8:00	101.4			104		20		
11:00	99.8			100		22		
P.M.	Temperature			Pulse		Respiration		
3:00	104.2			100		24		
4:00	105.0			132		36		
7:00	101.0			100		24		
12:00	105.4			116		28		

Urinalysis: color, amber; transparency, turbid; specific gravity, 1.016; reaction acid; albumin, 2 plus; sugar, diacetic acid, and indican negative; occasional squamous epithelium, few granular casts.

Transfusion: 500 c.c. citrated blood.

Dec. 11. Leukocytes—1,500; erythrocytes—4,150,000; hemoglobin—85% Sahli; color index—1.0. Differential count:

BAS.	EOS.	MYEL.	JUV.	STAB.	SEG.	LYMPH.	MONO.	
—	—	—	—	—	—	100	—	(Only 50 cells were found for the differential count)
A.M.				Temperature		Pulse		Respiration
4:00.				105.4		106		30
6:30				104.6		112		30
8:30				105.2		94		24
P.M.								
3:00				103.6		128		28
7:00				105.4		180		40

Transfusion: 500 c.c. citrated blood.

Patient expired Dec. 11 at 11:30 P.M.

Autopsy was performed by Dr. Gradwohl. Report follows: The body is that of an aged white woman in good state of nutrition. There are no marks of injury.

The liver is visible three fingers' breadth below the free border of the ribs. Right ovary: very large, $3\frac{1}{2} \times 4$ inches. It is occupied by multilocular cysts. Left ovary: smaller than right; and more of the structure remains. Contains one clear cyst, one chocolate cyst, and coagulated blood. Tubes: normal. Uterus: small, infantile; few intramural fibroids present. Stomach: distended; the extrahepatic biliary passages are open. Right kidney: tunica propia strips without tearing. The fatty capsule is abundant, surface is smooth, stellate veins are engorged, and a cut section shows a wide cortex with fatty changes. Left kidney: same as the right kidney except for considerable scarring. Spleen: small and very firm. A cut section shows that the pulp does not come off on the knife. Trabecular markings are prominent and the spleen is chronically inflamed. Gall bladder: contains thin light colored bile. Liver: enlarged; the cut section shows fatty changes. Pancreas: small.

Upon opening the chest cavity and incising the bone marrow, it is seen to be atrophic; very little red marrow is visible. Marrow taken for microscopic examination.

Lungs: approximate the median line. The right upper lung is somewhat firm, the lower lobe feels like consolidation, the upper lobe is cyanotic and edematous; the lower lobe is hypostatic, and the middle lobe is very edematous. The left lung, upper lobe, is emphysematous. The lower part of the upper lobe is hypostatic and the lower lobe is very red and hypostatic.

Upon opening the pericardial sac it is found to contain about 20 c.c. of clear yellow fluid. There are small petechial hemorrhages on the inside of the parietal pericardium. The left chest contains no free fluid or adhesions. The right chest shows the same. Heart: somewhat fatty with one milk spot on the presenting surface of the left ventricle; right auricle: overdistended with fluid blood and clots; right ventricle: contains fluid blood; left auricle: overdistended with dark clots; left ventricle: empty. Right chamber: somewhat dilated; left chamber: shows a rather thin ventricular wall. Valves: normal. Intima of the aorta: mild degree of arteriosclerosis. Coronary artery: not occluded. There is a mild degree of arteriosclerosis.

Anatomic Diagnosis: (1) Arteriosclerosis of a mild degree; (2) hypostatic pneumonia; (3) fatty degeneration of the liver; (4) cystic ovaries; (5) fibroid tumor of the uterus.

The diagnosis of agranulocytosis cannot be confirmed by anatomic evidence; it must be confirmed by bone marrow examination. The result of these studies will be reported later.

Examination of autopsy tissue:

Tumor of the uterus: pure fibroma.

Left kidney: slight increase in interstitial structures. There is a cloudy swelling in the epithelium of the tubules and a small collection of lymphocytes around a few of the glomeruli.

Heart: definite increase in connective tissue between muscle bundles. There is fibrosis of ventricular wall.

Liver: a great deal of fat between the globules. There is a slight degree of liver cirrhosis. This is a fatty and cirrhotic liver.

Differential counts were made on the bone marrow on two different slides.

This marrow is composed mainly of fat with less than the normal reserve of orthochromatic erythrocytes. Cells are scattered and scarce.

Slide (1)	Neutrophilic myelocytes -----	2%
	Neutrophilic juveniles -----	1%
	Lymphocytes -----	95%
	Orthochromatic normoblasts -----	2%
Slide (2)	Myeloblasts -----	8%
	Promyelocytes -----	4%
	Neutrophilic myelocytes -----	6%
	Neutrophilic juveniles -----	1%
	Lymphocytes -----	77%
	Plasma cells -----	1%
	P. normoblasts -----	3% (1 in karyorrhexis)

There were more cells on the second slide than on the first, but the bone marrow showed less than the usual number of cellular elements.

The Bone Marrow in Agranulocytosis.—The bone marrow shows variable pictures in different types of agranulocytosis. There may be a hyperplastic or aplastic type or a reticuloendothelial type. The usual type is aplastic, which has a serious prognosis. A hyperplastic type probably indicates a favorable outcome. In the aplastic type the bone marrow shows many lymphocytes and plasma cells. In the hyperplastic type, there are numerous myeloblasts and granulocytes in the bone marrow spread. Roberts and Kracke¹ saw degenerative myeloblasts in cases of agranulocytosis reported by them. There is a type of reticuloendothelial change in bone marrow in some cases of agranulocytosis which shows marked hyperplasia of the reticuloendothelial system in addition to the presence of lymphocytes and plasma cells in the bone marrow. These reticuloendothelial cells are clasmatoctytic in appearance.

The blood picture that is typical of this disease shows a differential count of, let us say, 90 per cent lymphocytes and 10 per cent monocytes with no granulocytes whatsoever.

The course of the disease is a leukopenia following the angina; the bone marrow practically ceases to deliver neutrophilic cells. As the disease progresses, the angina develops into gingivitis and tonsillitis and may finally lead to a gangrenous condition. The mortality was previously high, around 90 per cent. With improvement the count rises rapidly, and the patient goes on to recovery. In many cases there are periods of remission with subsequent recurrences.

The Treatment of Agranulocytosis With Penicillin.—

Prior to 1942 the chief aim of physicians in cases of agranulocytosis was to stimulate leukopoiesis by various agents, pentose nucleotide, yellow bone marrow, liver extract, and blood transfusions. These remedies usually proved inadequate and the mortality rate in agranulocytosis remained high.

In 1942 Dameshek and Wolfson² introduced a new policy, that is, not to worry about the bone marrow but to prevent or control the secondary infection; if infection and toxemia can be controlled, the bone marrow may

¹Roberts, S. R. and Kracke, R. R.: *Ann. Int. Med.* 5: 4, 1931.

²Dameshek, William and Wolfson, L. E.: *Am. J. M. Sc.* 203: 819-823, 1942.

take care of itself and recover spontaneously. Thus has developed the rationale for the use of sulfonamides and penicillin. Seven cases of agranulocytosis were successfully treated by sulfonamides but, because sulfonamides themselves may induce agranulocytosis, medical authorities turned to penicillin as an equally effective and safe remedy. It was found that penicillin could be used without harm in the presence of granulocytopenia, or even of agranulocytosis, resulting from severe infections.

One of the most interesting reports on this subject is by Boland, Headley, and Hench.¹ Here they detailed an account of a case of rheumatoid arthritis in which treatment with gold salts resulted in severe agranulocytosis. The total leukocyte count was 3,400 per cu.mm. of blood and no neutrophils were present. With a rapidly progressive folliculitis with marked toxemia, the case appeared very grave. Penicillin therapy was instituted, resulting in a remarkable and dramatic improvement. On one day these physicians thought the patient was dying and the next day he was almost well.

In an entire group of 15 cases, including this case, reported in the literature, the total dosage of penicillin, usually given intramuscularly, varied from 132,000 to 6,480,000 units given within about four to twenty-one days. Recovery within about four to ten days occurred in every case.

It is concluded at this time that penicillin constitutes the most powerful remedy at hand for the prevention or control of secondary infection in agranulocytosis. The mortality rate from this disease, untreated or inadequately treated, has been 70 to 75 per cent; the mortality rate when the disease was treated intensively by leukopoietic agents was still 35 per cent or more. With the added use of penicillin the mortality rate has been reduced tremendously.

More important than the treatment of agranulocytosis is its prevention by avoiding the unnecessary use of drugs which cause this condition. If the drug has to be used, then careful hematologic monitoring is imperative.

Infectious Mononucleosis

Infectious mononucleosis, which has often been confused with acute lymphocytic leukemia, was first reported in the literature by Filatow,² in 1885. Later, in 1889, Pfeiffer³ described it again, calling attention to an infectious process characterized by very definite symptoms, to which he gave the name glandular fever. West⁴ reported an epidemic of ninety-six cases limited to children, with no evidence of throat infection. Tidy and Morley⁵ reported more cases and described the disease again. They noted the enlargement of the axillary and inguinal glands but not the abdominal signs. Tidy⁶ described the epidemic nature of infectious mononucleosis with an incubation period of from 5 to 15 days. Contact infection occurs only in the early stages of the disease, and direct contact or throat droplet infection is probably the mode of transmission. Sprunt and Evans⁷ reported cases of this same disease

¹Boland, E. W., Headley, N. E., and Hench, P. S.: *Proc. Staff Meet., Mayo Clinic* 21: 197-206, 1946.

⁷Sprunt, T., and Evans, F. A.: *Bull. Johns Hopkins Hosp.* 31: 410, 1920.

occurring in young adults with infection of the upper respiratory tract with systemic reaction always present, together with the general glandular enlargement with frequent enlargement of the spleen. All cases showed a lymphocytosis and moderate increase in the total number of white blood cells, together with a blood picture very much like that found in acute leukemia. There was no hemorrhage or severe anemia in any case reported. Longcope⁷ reported cases with acute throat infection but no leukocytosis and very moderate increase in lymphoid cells. Downey and McKinlay⁸ reported nine cases with a study of the hematologic findings. Since 1923 a number of cases have been reported in the literature, together with two contributions, one by Bunnell⁹ and one by Paul and Bunnell,¹⁰ in which they pointed out a definite laboratory test, known as the *heterophile antibody test*, which will be described later.

So far as etiology is concerned, a number of causative organisms have been reported, notably *Listerella monocytogenes*, isolated from rabbits by Murray,¹¹ and *Bacterium monocytogenes* isolated from an apparent case in man by Nyfeld.¹² Other organisms have been described but have not been definitely established. Many believe this to be a virus disease.

Julianelle¹³ also identified *Listerella monocytogenes* which was identified by C. A. Pons from the blood of a patient with infectious mononucleosis. He attempted to determine the significance of *Listerella* in this disease by (a) blood cultures from patients; (b) agglutination tests with the patient's sera; (c) experimental infection in different animals; and (d) stimulation of heterophile antibody by *Listerella* under various conditions. Except for the first culture, all others failed to give any growth. Regarding agglutination tests it was observed in thirteen instances, three times with the "ruminant strain," and ten times with the "rodent strain." He was not able to reproduce in the animals a certain quality to the lymphocytes which is seen in infectious mononucleosis. He did not encounter the so-called Rieder cell in experimental infection. In no instance were the sera found to contain the heterophile antibody despite their high titer for *Listerella monocytogenes*. Julianelle, in other words, concluded that at that time he could not state whether or not infectious mononucleosis of man is an example of *Listerella* infection.

Examination of the biopsy material from lymph nodes of patients with infectious mononucleosis shows that the hyperplasia of lymphocytes is not as extensive as in cases of lymphadenosis. The atypical structure of the lymphocytes and the increase in their number indicate that the disease is due to infection with some organism or virus which has a very specific stimulating effect on the lymphocytes and reticulum and a depressing effect on the granulocytic system.

Blood Picture.—There is no particular change in the number of red cells, the amount of hemoglobin, or the number of blood platelets in infectious mononucleosis. Leukopenia is striking in the beginning. There is usually a

eukocytosis coincident with enlargement of the lymphatic glands. The differential count shows a high lymphocyte count, often reaching a very high level, with the appearance of immature forms, particularly binucleated cells. (See Plate XXIII.) At this time, the case is almost indistinguishable from lymphocytic leukemia. Downey and McKinlay¹ made an exhaustive hematologic study. They emphasize that the lymphocytosis of infectious mononucleosis has a typical cell which shows varying characteristics in different patients. They divided their patients into three groups, entirely dependent upon the type of lymphocytes present in the blood picture.

The cells of their Type I may be described as follows: cells were not excessively large; they were all atypical, pathologic forms, including even the medium-sized lymphocyte, which has a more basophilic and vacuolated cytoplasm than is usual for these cells. The size and form of the nucleus are of little value in determining genetic relationships or stage of differentiation of the cells, but the quantity and distribution of chromatin and its relation to the parachromatin are of great importance. The characteristic cells are highly differentiated, mature, and are "leukocytoid" lymphocytes, rather than immature "lymphoblasts." The chromatin in the nucleus forms a coarse network of heavy strands and masses which are not sharply separated from the parachromatin. This gives the nucleus a cloudy appearance which is quite characteristic for the lymphocyte. In some cells there is a slight condensation of the chromatin with corresponding separation from the parachromatin. The dense rounded or angular blocks of chromatin characteristic of the nuclei of plasma cells are the result of further condensation. In some of the larger cells, there may be a slight tendency toward a more diffuse arrangement of the chromatin but this is never sufficient to warrant classification of the cell as a lymphoblast or particularly immature cell because the lymphocytic nature of the nucleus always remains evident. The nuclei of the larger cells are frequently placed excentrically and are generally lobulated or indented. The smaller cells also have irregular nuclei. Occasionally, a cell may be found with a very wide and pale cell body consisting mostly of hyaloplasm, but with the nucleus of a mesolymphocyte. The cytoplasm shows a varying degree of basophilia, but most of the cells are very basophilic, much more so than is usual in the normal large lymphocyte or large monocyte. There is an occasional cell with the nuclear and cytoplasmic characters of a plasma cell, but most of them do not have the nuclear structure of plasma cells, although their spongioplasm may be just as basophilic. Frequently there are seen one or more azurophil granules embedded in the hyaloplasm of this region, giving the whole structure the appearance of a centrosphere.

The Type II cases show a nucleus similar to that of the plasma cell. The chromatin strands are very coarse and there are several dense, rounded or angular masses of chromatin among them. This arrangement of chromatin in dense masses is quite characteristic of the nuclei of plasma cells; the nuclei of many of the atypical cells of this series approach the plasma cell type more or less. They have more of a washed appearance. The cytoplasm in Type II is different from that of Type I, it has fewer vacuoles and its spongioplasm

¹Downey, H., and McKinlay, C. A.: *Arch. Int. Med.* 32: 82, 1923,

has a smoother appearance which does not give the foamy, spongy, and stippled effect noted in the cells of Type I. It is generally less basophilic. The nucleus is rarely lobulated.

Type III cases show more leukemic features than any of those described under Types I and II. These Type III cases show large, atypical cells, with vacuolated cytoplasm; in some cells, it is quite basophilic. The leukemic features are particularly interesting. About 1 per cent of the lymphoid cells contains a single large vacuole with an azurophil rod, in addition to smaller vacuoles distributed rather evenly throughout the cytoplasm. The nuclei of some of the atypical cells are dedifferentiated to such an extent that some of them closely approximate the lymphoidocytic type.

In general, the abnormal cell characters in this disease are due to higher differentiation and special cell activity. The peroxidase test on these cells is negative, which would incline one to believe in their lymphocytic origin. Osgood¹ directed particular attention to the nuclear fenestrations in the mature small lymphocytes of this disease. These fenestrations are multiple holes and are considered by Osgood of definite diagnostic importance. The hemograms in Table 63 from a case of infectious mononucleosis illustrate the hematology of the disease.

The Heterophile Antibody Test

Method I.—Owing to the difficulty of making an absolute diagnosis on clinical and cytologic grounds, the suggestion of a serologic diagnostic test, proposed by Paul and Bunnell* in 1932, was hailed with a great deal of satisfaction. This test is based on the presence of sheep heterophile antibodies in the blood of the patient. The heterophile antibody concerned may be defined as an antibody reacting with an agent other than and phylogenetically unrelated to the specific antigen responsible for the production of the antibody in question. The presence of increased sheep heterophile antibodies in the blood in cases of infectious mononucleosis was rapidly confirmed by a number of independent investigators. It is important to know that such antibodies were not increased in those diseases to which infectious mononucleosis so often bears a close resemblance. This test was originally devised by Paul and Bunnell and modified by Stuart and co-workers.† It is performed as follows:

Add 0.5 c.c. of 1 per cent suspension of washed sheep cells to 0.5 c.c. of serial dilutions of the patient's serum. The tubes are incubated at 37° C. for 2 to 4 hours and the degree

*Paul, J. R., and Bunnell, W. W.: *Am. J. M. Sc.* 183: 90, 1932.
†Stuart, C. A., Burgess, A. M., Lawson, H. A., and Wellman, H. E.: *Arch. Int. Med.* 54: 199, 1934.
¹Osgood, E. E.: *Proc. Soc. Exper. Biol. & Med.* 13: 28, 1935.

of agglutination noted. In the routine diagnosis of infectious mononucleosis it is not advisable to incubate the tests overnight in the icebox since, as pointed out by Stuart, Tallman, and Brintzenhoff,[†] many normal sera with little or no sheep cell titer at 37° C. may show a titer as high as 1:160 when tested at 5° C. With confirmatory clinical and cytologic evidence, a titer ranging from 1-80 to 1-10,000 at 37° C. is with few exceptions a positive diagnosis of this disease.

The following technic for the heterophile antibody test adapted by Kracke¹ from Davidsohn, Bernstein, Paul, and Bunnell, has been found more serviceable by us:

Technic.—

Eleven tubes are required for the test, ten tubes for the serial dilutions of the patient's serum, and the eleventh tube for a control over saline and sheep cells used.

To tubes 2, 3, 4, 5, 6, 7, 8, 9, 10, and 11 add 0.5 c.c. of physiologic saline; tube 1 receives no saline. Tube number 1 receives 0.5 c.c. of patient's inactivated serum (heated to 55-56° C. for 15 minutes). Tube 2 receives 0.5 c.c. of patient's inactivated serum. The contents of tube 2 are mixed carefully by drawing in and out of the pipette and 0.5 c.c. pipetted to tube 3. Tube 3 is mixed in the same manner, by drawing in and out of a pipette and 0.5 c.c. pipetted to tube 4. Tube 4 is mixed carefully and 0.5 c.c. pipetted to tube 5, and this is continued through tube 10. Tube 10 is mixed and 0.5 c.c. discarded, tube 11 receiving no serum. Dilution of serum in the 10 tubes is now as follows: (1) undiluted; (2) 1:2; (3) 1:4; (4) 1:8; (5) 1:16; (6) 1:32; (7) 1:64; (8) 1:128; (9) 1:256; (10) 1:512. No serum in tube 11. To each of the eleven tubes 0.5 c.c. of a 2% suspension of sheep cells is added. The cells are prepared in physiological saline. (Wash three times immediately before using by adding three times their volume of physiologic saline and centrifuging until firmly packed. The supernatant fluid is removed and the 2% suspension is made by adding 49 volumes of saline.)

After the addition of the sheep cell suspension 1 c.c. of saline is added to each of the eleven tubes. The total quantity in each tube is now 2 c.c.

The tubes are shaken thoroughly and incubated in a water-bath at 38° C. for 1 hour and placed in a refrigerator overnight. One hour at room temperature may be substituted for the refrigeration period, but the test should be checked after refrigeration.

The results are read macroscopically after gently inverting the tubes three times. The results are best reported in degrees. The agglutination is considered as three-plus when the cells remain in a single large clump, as two-plus when the clumps are clearly visible but suspended in clear fluid, and as one-plus when the agglutination can be demonstrated only under a microscope. Always report the strength of the dilution and the degree of the reaction.

The particular usefulness of this test in public health laboratories was reported by Stuart and Mickle.² They state that while this test is diagnostic in a large majority of cases, yet conditions exist under which a serum of moderately high or even very high titer may be erroneously reported positive. Sheep heterophile antibodies similar in character to those found in infectious mononucleosis had been previously demonstrated by Davidsohn³ and many others in the blood of individuals after injections of native or therapeutic horse serum, particularly when serum sickness developed. Davidsohn⁴ has also shown that such antibodies might persist in the blood of a patient for a year or more after treatment with horse serum. Should the serum from such an individual be submitted for an infectious mononucleosis test at any time

⁴Davidsohn, I.: *J. Immunol.* 16: 359, 1929.

previous to the disappearance of the sheep heterophile antibodies associated with the serum sickness, the routine procedure described would be valueless in proving that diagnosis. Stuart, Welch, Cunningham, and Burgess⁵ found that the sheep antibodies in serum sickness were completely adsorbed by emulsions of guinea pig kidney whereas those of infectious mononucleosis were not. Should an apparent infectious mononucleosis case with a history of serum treatment give a high sheep cell titer, it should be titrated as outlined in Method II, below. If the sheep agglutinins are completely or almost completely removed by adsorption with guinea pig kidney, heterophile antibodies of the infectious mononucleosis type are not present. If, on the other hand, the original sheep cell titer of the serum is not significantly reduced by the adsorption, the heterophile agglutinins of infectious mononucleosis are present.

Method II.—The patient's serum should be titrated for antish sheep agglutinin in three ways: (a) unabsorbed, (b) after absorption with guinea pig tissue, and (c) after absorption with beef tissue. If all three titrations are not made, there might be some confusion between the diagnosis of infectious mononucleosis and serum sickness, horse serum reaction, leukemia, Hodgkin's disease, tuberculosis, purpura, and the lymphomas.

Equipment.—

- 24 test tubes, 75 by 12 mm.
- 1 test tube rack
- 4 pipettes, 0.25 c.c.
- 2 pipettes, 0.50 c.c.
- 2 pipettes, 1.0 c.c., graduated in 0.1 c.c.
- 2 sterile syringes, 1 and 2 c.c.
- 2 sterile needles, 20 gauge
- 2 dropper pipettes
- 2 centrifuge tubes, 15 c.c., graduated
- 1 water bath regulated at 56° C.
- 1 centrifuge
- 1 clock or watch
- 1 viewing box such as is used for blood grouping tests

Reagents.—

0.85% Sodium Chloride Solution.

Patient's Serum.—

Obtain in the usual manner, and inactivate in a water bath at 56° C. for 30 minutes.

2.0% Sheep Red Blood Cells.—

Make either from freshly secured blood or prepare from preserved sheep cells.

Place 1.5 c.c. of well-mixed suspension of sheep cells into a 15 c.c. centrifuge tube.

Wash three times in saline or until the supernatant saline is clear and colorless.

This should leave about 0.3 c.c. of packed sheep cells. Dilute 0.3 c.c. of sheep cells with saline to 15 c.c. to make a 2% suspension.

Guinea Pig Kidney Antigen.*—

This can be obtained ready for use.

Beef Cell Antigen.*—

This can be obtained ready for use.

*An excellent preparation of guinea pig kidney antigen and beef red cell antigen is procurable from Certified Blood Donor Service, Jamaica 35, N. Y.

⁵Stuart, C. A., Welch, Henry, Cunningham, John, and Burgess, A. M.: Arch. Int. Med. 58: 512, 1936.

Technic.—**(A) Titration of Unabsorbed Serum.—**

Place 6 test tubes in a test tube rack.

Place 0.4 c.c. of saline in the first tube.

Place 0.25 c.c. of saline in each of the other tubes.

Add 0.1 c.c. of patient's inactivated serum to the first tube.

Mix by drawing into and out of a pipette several times.

Transfer 0.25 c.c. from the first to the second tube, and mix again. (For exact method of handling, see section on blood grouping, page 1015.) Transfer 0.25 c.c. to the next tube and mix.

Continue transferring and mixing through tube 6. This leaves 0.5 c.c. in tube 6. Remove and discard 0.25 c.c. from tube 6.

Add 0.1 c.c. of washed sheep cell suspension to each tube.

Shake well and let stand at room temperature for 2 hours.

Examine for clumping of the red blood cells after gently shaking the tubes.

According to Davidsohn (adapted from Stuart and co-workers), the final dilutions are 1:7, 1:14, 1:28, 1:56, 1:112, etc. (This apparently includes the quantity of sheep cells used: first tube contains 0.05 c.c. serum in a total of 0.35 c.c.)

The titer is the weakest dilution of the serum which gives clumping that is visible to the naked eye.

(B) Titration of Serum Absorbed by Guinea Pig Antigen.—

Shake the suspension of guinea pig antigen thoroughly and place 1 c.c. in a test tube.

Add 0.2 c.c. of inactivated serum.

Shake the tube well, and centrifuge at high speed for 5 minutes.

Transfer the supernatant liquid with a capillary pipette to a clean test tube. This is the absorbed serum.

Place 0.25 c.c. of saline in each of 6 tubes.

Add 0.25 c.c. of absorbed serum to tube 1.

Mix and transfer serially 0.25 c.c. to each tube. Discard the last 0.25 c.c. from tube 6.

Add 0.1 c.c. of washed sheep cells to each tube.

Shake well and let stand at room temperature for 2 hours.

Examine for clumping of the red cells after gently agitating the tubes.

The final dilutions are 1:14, 1:28, 1:56, etc. (includes the added sheep cells).

The titer is the weakest dilution of serum which gives clumping visible to the naked eye.

(C) Titration of Serum Absorbed by Beef Cell Antigen.—

Proceed exactly as for (B), above, using thoroughly shaken beef blood cell antigen in place of the guinea pig antigen.

Interpretation of Results.—

If unabsorbed serum is used, titers below 1:56 are usually of no clinical significance; a titer of 1:56 is suggestive of infectious mononucleosis; titers above 1:56 are indicative of infectious mononucleosis. Since exceptions occur, it is recommended that the differential absorption tests be performed.

Beef cell antigen absorbs the infectious mononucleosis (I.M.) antibody completely, while guinea pig antigen does not. For example, if the titer with unabsorbed serum is 1:56, and the patient has infectious mononucleosis, the titer after beef cell absorption will be 0 or nearly 0, while after guinea pig absorption it will be 1:56, 1:28, or even 1:14, but no lower.

It must be remembered that the specific infectious mononucleosis antibodies are not present throughout the disease, and they should be sought on more than one occasion if the clinical symptoms and the blood findings are suggestive of infectious mononucleosis.

Periodic or Cyclic Neutropenia

There is a group of *chronic* recurrent neutropenias in which no drug or other etiological factor has been found to explain such recurrences. These were described by Reimann,¹ who has been interested in other forms of cyclic disease such as cyclic fevers, and periodic peritonitis. The striking fact about the leukopenia is that it occurs in regular cycles of three to four weeks. Symptomatology is variable and tends to mimic that seen with agranulocytosis, consisting of stomatitis, acute lymphadenopathy, fever, and fatigue. Sore throats and joint pains may be present. Physical findings are not unusual except for the lymphadenopathy and occasional mild splenomegaly. The white blood count varies between 2,000 and 4,000 per cu. mm., with a neutropenia from 0 to 16 per cent.

Primary Splenic Neutropenia

Primary splenic neutropenia was first described in 1942 by Wiseman and Doan.² The outstanding feature of the syndrome is that there is neutropenia associated with splenomegaly. Other symptoms have been quite variable. A fair number of cases have been added to the original number observed by Wiseman and Doan. The clinical picture so far as symptoms and physical findings are concerned is not well defined. The bone marrow is generally hyperplastic. It is our impression that these cases may represent a form of immunohematologic disease in which the leukocyte is a predominantly affected cell.

Acute Infectious Lymphocytosis

Carl H. Smith reported³ an account of a new disease entity, acute infectious lymphocytosis. He reported two cases in 1941 and saw four cases during March, 1943. The fact that three of the patients were members of one family and one a hospital contact impressed him with the possible communicability or infectiousness of the disease. Other cases have been reported at various hospitals in New York City where these first cases were noted.

This is a disease with an elevated leukocyte count persisting for approximately 3 to 5 weeks. The clinical course varies in intensity. This disease can be separated from infectious mononucleosis, acute lymphocytic leukemia, and miscellaneous infections associated with lymphocytosis. The disease has a possible incubation period of 12 to 21 days and may be marked by varying degrees of constitutional reaction at the onset, such as vomiting, irritability, and fever, together with acute abdominal signs and symptoms and occasionally signs of involvement of the nervous system. There is no lymphadenopathy nor is there a palpable spleen. The heterophile agglutination

¹Reimann, H. A.: *Blood* 4: 1109, 1949.

²Wiseman, B. K., and Doan, C. A.: *Ann. Int. Med.* 16: 1097, 1942.

³Smith, Carl H.: *J. A. M. A.*, June 3, 1944; *Lab. Digest* 8: 6, 1944.

reaction is uniformly negative. In two of the cases the biopsy of a lymph node showed strikingly similar microscopic appearance. An outstanding feature in these biopsies was a striking proliferation of the reticuloendothelium of the sinuses, which were blocked by masses of cells. In addition, the lymph follicles showed a number of changes. Some of the germinal centers showed a hyaline degeneration of varying degree. Many of the follicles were notably inconspicuous, and in some sections they were practically obliterated. A feature common to most of the cases was infection of the upper respiratory tract.

The striking feature of these cases was the hyperleukocytosis with relative and absolute lymphocytosis persisting for a prolonged period. Normal small lymphocytes accounted for this increase and presented the most important diagnostic element of the blood picture.

The differential diagnosis from leukemia was based largely on the absence of lymphoblasts. Lymphoblasts are usually round, large, and uniform in size, and show a distinct nuclear pattern. Besides, in acute lymphocytic leukemia with a hyperleukocytosis of the magnitude found in infectious lymphocytosis the blood would show a severe anemia and a decrease in platelets, and enlargement of the spleen and lymph nodes would be noticed.

Examination of the bone marrow also serves to differentiate between leukemia and this disease. In acute lymphocytic leukemia in children, marrow aspiration shows complete replacement of the bone marrow by lymphoblasts. In acute infectious lymphocytosis, on the other hand, the myeloid and erythroblastic elements are present in normal proportions and the only abnormality is the presence of normal lymphocytes in increased percentage.

In the first case, the first blood count showed 45,000 white cells per cubic millimeter, 45 per cent neutrophils, and 48 per cent lymphocytes. In a few hours, the white count rose to 55,400 with 72 per cent lymphocytes. The total count in some cases ran as high as 68,300, and the lymphocytosis amounted to as much as 90 per cent in one case.

The elevated blood levels persist from three to five weeks. The normal lymphocytes in this disease are in sharp contrast to the atypical and abnormal lymphocytic elements in infectious mononucleosis and to the lymphoblasts in leukemia.

The heterophile agglutination reaction was uniformly negative in these cases and the serologic reactions were negative for lymphocytic choriomeningitis and for influenza A and B virus.

In all cases the disease was uncomplicated and had a uniformly favorable outcome.

The evidence presented by Smith clearly indicates that acute infectious lymphocytosis is a heretofore unrecognized communicable disease in which the blood picture serves as an expression of the infection.

The author saw one case of this type in 1942 which puzzled him very much. This report by Smith clarified the situation in his mind regarding whether the case was really a new type of disease or whether it was a simple infectious condition with a concomitant lymphocytosis.

TABLE 64.—MEANS OF DIFFERENTIATING SOME CONDITIONS CHARACTERIZED BY LYMPHOCYTOSIS

	PERTUSSIS	ALBUKEMIC LEUKEMIA	CHRONIC LYMPHO- CYTIC LEUKEMIA	ACUTE LYMPHO- CYTIC LEUKEMIA	ACUTE INFECTIOUS LYMPHO- CYTOSIS	INFECTIOUS MONO- NUCLEOSIS	AGRANULO- CYTOSIS	IDIOPATHIC APLASTIC ANEMIA	PERNICIOUS ANEMIA	ENDOCRINE DISTURB- ANCE	CHRONIC TUBER- CULOSIS

The Lupus Erythematosus ("L.E.") Cell Phenomenon

The often bizarre clinical patterns observed in disseminated lupus erythematosus have made the diagnosis of this disease difficult, especially when the typical skin manifestations are absent. A diagnostic aid was added with the finding of the "L.E." cell in bone marrow by Hargraves and associates.¹ These bone marrow findings were soon verified^{2, 3} and others^{4, 5} were able to find these cells in the peripheral blood of patients with lupus erythematosus. Since the original description of this unusual cell, it has been shown that the serum (or plasma) of patients with lupus erythematosus will reproduce the phenomenon when added to the bone marrow^{4, 6} or the blood^{7, 8} of normal persons or of patients suffering from diseases other than lupus.

These observations led to the conclusion that the abnormal factor was present in plasma and Haserick⁹ identified its association with the gamma globulin fraction. Kurnick and associates¹⁰ have reported that in addition to the specific factor present in Fraction II of L.E. sera, other elements participate in the phenomenon, namely (a) desoxyribonuclease, (b) an inhibitor of desoxyribonuclease, and (c) a factor or factors in Fraction III of normal and L.E. sera. Kurnick and co-workers¹¹ have followed these ideas with determination of the susceptibility of leukocytes from different animal species to alteration by lupus erythematosus serum. These observers found that the leukocytes of the chicken and horse were the most susceptible and that those of the guinea pig and dog were highly susceptible. In all these species, the demonstration of L.E. cell formation was much more striking than when using human leukocytes and they recommend an animal substrate of leukocytes for performing the "L.E." cell test.

Very early in the observations on the "L.E." phenomenon it was realized that the abnormal cells were not dependent on anticoagulant and we were able to demonstrate "L.E." cells in sections,¹² as have others.¹³ We realized in these early observations that the phenomenon was essentially an *in vitro* phenomenon, requiring contact of L.E. serum factors with leukocytes for a period of at least 10 to 15 minutes outside the body. We were not able to demonstrate L.E. cells in blood or bone marrow preparations made *immediately* after withdrawal.

The use of guinea pig or dog blood as a substrate is suggested for laboratory use as a means of increasing the sensitivity of the test (see page 830).

The finding of L.E. cells in the peripheral blood or bone marrow of any patient imposes a diagnosis of lupus erythematosus, although a few exceptions to this statement are to be found: individual cases of dermatitis herpetiformis,¹⁴ pernicious anemia,¹⁴ leukemia,¹⁵ multiple myeloma,¹⁶ and primary amyloidosis.¹³ Haserick¹⁷ contaminated plasma samples with fungi and simulated the L.E. cell phenomenon. Walsh and Zimmerman¹⁸ have reported three cases of severe penicillin reaction in which L.E. cells were found in the bone marrow and the plasma factors in the plasma. More recently a lupuslike syndrome has been described in patients treated with hydralazine (Apresoline) for hypertension,¹⁹ in which L.E. cells can be demonstrated. The phenomenon disappears after withdrawal of the drug. Despite these few exceptions, the finding of L.E. cells should be strong evidence of the diagnosis of lupus unless proved otherwise. On the contrary, failure to demonstrate such cells does not militate against such a diagnosis. Our experience has been that L.E. cells are most abundantly present in the acute cases of lupus, and are particularly easy to demonstrate in the terminal phases of the disease. The finding of L.E. cells in patients in remission is variable. At times we have noted inexplicable variations in numbers of L.E. cells. Occasional patients are seen whose preparations contain numerous L.E. cells on one day and only rare forms the following day. We have observed, as have others, so-called precursor forms in some of our preparations. However, we report such forms as only suggestive and do not make a diagnosis of L.E. cells unless they are typical. As with many other laboratory searches, the incidence of positive L.E. preparations is proportional to the vigor with which the pursuit is made, and often many preparations must be made on a given patient before these cells are found. Caution must be exercised in discriminating between erythrophagocytosis by polymorphonuclear leukocytes and L.E. cells. In the former instance, the bodies are the orange or salmon pink of red cells, whereas in the latter, the ingested bodies are a violaceous color with Wright-Giemsa stain.

In unpublished studies in 1950, we originally demonstrated* L.E. cells in sections of bone marrow and performed histochemical studies on this material. In addition to typical L.E. cells, there were found free bodies which showed all of the characteristics of the phagocytized elements. With routine hematoxylin and eosin, the L.E. bodies stained a fuzzy homogeneous lavender blue, whereas normal nuclei stained a dark blue. When only Schiff reagent was applied to this section material, neither normal nuclei nor the bodies took the stain; however, preliminary treatment with hydrochloric acid resulted in brilliant fuchsinophilic staining. In sections treated with periodic acid and Schiff reagent, followed by counterstaining with Mayer's alum hematoxylin, the nuclei of intact cells took the characteristic hematoxylin stain but the L.E.

*Dr. Eli M. Nadel, U. S. P. H. S., carried out the histochemical studies.

Fig. 198.—Lupus erythematosus ("L.E.") cell phenomenon. Bone marrow spreads and tissue sections. 1, Spread of sternal marrow aspirate. An intracellular (a) and an extracellular (b) L.E. body are seen in addition to a degenerated nucleus (c). (Wright-Giemsa stain; $\times 940$.) 2, Paraffin section of the sternal marrow aspirate with an L.E. cell. (H & E has been treated with ribonuclease and stained with toluidine blue. L.E. body stains similarly to the nuclear material. ($\times 1,530$.) 3, Paraffin section as in 2. Tissue has been stained by the Fuelgen method. L.E. body stains similarly to the nuclear material. ($\times 1,530$.) 4, Paraffin section of kidney of a patient with clinical and autopsy diagnoses of disseminated lupus erythematosus. Sections have been treated with hyaluronidase and stained by the Hotchkiss method. Intra- and extracellular L.E. bodies were seen. ($\times 280$.) 5A, Higher power of 4A, showing a typical L.E. cell. ($\times 1,530$.) (From the collection of H. Agrest.)

PLATE XXI.—LUPUS ERYTHEMATOSUS ("L.E.") CELLS.

The cluster in the upper right-hand corner is a typical "rosette" with an L.E. body in the center. The cell containing a body, in the lower right-hand corner, is a "tart" cell, which is not pathognomonic of lupus erythematosus. Source of material, bone marrow. $\times 800$.

bodies were homogeneous and a muddy, reddish purple. Neither saliva nor hyaluronidase altered the periodic acid-Schiff positive staining properties of the L.E. bodies. The extracellular and intracellular bodies were negative for iron and for mucin.

From these studies we concluded that the L.E. bodies which we saw in sections were identical to the "hematoxylin staining" bodies first described by Gross²⁰ in tissue sections and in subsequent studies by Genzler and Fox²¹ and Klemperer and associates.²² Cytochemical studies on these hematoxylin bodies²³ were in close correspondence with our studies of kidney displaying hematoxylin bodies. This kidney material was subjected to the same histochemical studies as our bone marrow material; the bodies in the two specimens showed corresponding cytochemical results, a postulate prophesied by Klemperer and co-workers.²³ We suggested at that time that our histochemical studies characterized the L.E. bodies as having approximately 72 per cent nucleoprotein, the percentage suggesting a cell with a relatively large nucleus and a sparse cytoplasm as the source of the L.E. cells. The lymphocyte could well fit this description, its altered nucleus forming the L.E. body. We then visualized the formation of L.E. cells as taking place in two stages. First, there is contact of the abnormal plasma factor with lymphocytes, stripping the cytoplasm of these cells and affecting the nucleus. This phenomenon can occur *in vivo* or *in vitro* and results in a free L.E. *body*. The second stage is the formation of the classical L.E. *cell* brought about by the phagocytosis of this *body* by polymorphonuclear leukocytes. This second phase is an exclusively *in vitro* phenomenon, dependent in part on the time of incubation.

Lee and associates¹³ came to similar conclusions, linking the L.E. cell to hematoxylin-staining bodies. They suggested that in the gamma globulin fraction of lupus plasma, there is a factor capable of altering desoxyribose nucleic acid metabolism. They believed that the inclusion body of the L.E. cell was altered nuclear material derived from polymorphonuclear leukocytes and lymphocytes. Rohn and Bond,²⁴ in supravital studies, found the L.E. inclusion body to be a mature autolyzed neutrophile.

Technic.—

The present method is adapted to routine clinical use.

Collect several c.c. of venous blood or 1 c.c. of bone marrow with an anticoagulant.

Mix thoroughly and allow to stand at room temperature for 1½ to 2 hours. If a 37° C. incubator is available, incubate the tube for 1½ hours.

Centrifuge at 1,500 r.p.m. for 10 minutes.

Aspirate the buffy coat along with a small amount of plasma.

Expel the mixture on a glass slide and touch the edges of successive clean slides to the pool and spread over the surface of slides, shaking these vigorously in the air for rapid drying.

Stain with Wright-Giemsa combination stain.

Demonstration of L.E. Cells, Method of Schultz et al.

Schultz and co-workers¹ have devised an ingenious microtechnic for demonstrating the L.E. cell phenomenon.

Place 2 or 3 drops of blood from a syringe or a finger puncture on a clean glass slide in 3 places on each slide.

Allow to clot.

Incubate at 37° C. for 20 minutes in a closed Petri dish containing moistened filter paper.

Wash the slide with a fine spray of physiologic saline to remove most of the clot, leaving thin "disks" adherent to the slide. Microscopic examination of these disks shows them to consist of polymorphonuclear leukocytes almost exclusively.

Immediately following the washing process, add several drops of the test serum or plasma to each disk, and place a cover slip over each preparation.

Place the slides again in covered Petri dishes containing moistened filter paper, and incubate at 37° C. for 1 hour.

Remove the cover slips and allow the slides to dry in the air by standing them on edge so that the excess fluid drains off.

Stain the slides by the Wright-Giemsa stain (or some modification of the Romanowsky stain), using neutral distilled water.

Scan under low-power magnification of the microscope for individual L.E. cells or for clumping of leukocytes with rosette formation.

If the specimens have been properly prepared, there will be leukocytes with normal morphologic characteristics other than those changes associated with the L.E. cell phenomenon.

If the leukocytes appear abnormal and the test is negative, there is doubt concerning the validity of the test on technical grounds, and the procedure should be repeated.

Schultz and associates recommend that a minimum of six disks be examined before considering the test negative. They state that the disk method was positive in some instances where other methods were negative, and that this method showed "either as many L.E. cells per high-power field as two other commonly used tests or more than the number seen by these methods."

Epidemic Hemorrhagic Fever

In June, 1951, United Nations Troops in Korea encountered an acute disease characterized by fever, prostration, vomiting, a variety of hemorrhagic manifestations, shock, proteinuria, and renal failure. A disease known to the Japanese as epidemic hemorrhagic fever and to the Russians as epidemic hemorrhagic nephroso-nephritis or Far Eastern hemorrhagic fever has been described in two U. S. Army Technical Bulletins on Korea and Manchuria.²

This disease was first described by the Russians who encountered it in Far Eastern Siberia in the middle 1930's. They found that the incubation period was generally ten to fifteen days, a single attack conferred immunity, and that the disease-producing agent would pass through a size N Berkefeld filter. It has been impossible to reproduce this disease in animals. In spite of the failure of animal experiments, it is suggested that hemorrhagic fever

¹Schultz, I., Baum, J., and Ziff, M.: *Proc. Soc. Exper. Biol. & Med.* 88: 300, 1955.

²TB MED 208, 1945 and TB MED 216, 1946.

may be transmitted to man by rodent ectoparasites, such as fleas, mites, ticks, and chiggers. These chiggers seem best to fit the observed epidemiologic facts.

The complete story on this interesting and new disease is found in the Symposium on Epidemic Hemorrhagic Fever by various authors.² Briefly, the clinical picture is characterized by sudden onset, in a person recently situated in an endemic area, of chills, fever, prostration, frontal headache, marked thirst, and myalgias. There is a marked facial flush, injection of the palate and conjunctivae, and petechiae of the conjunctivae, palate, axillary folds, and waistline. Proteinuria and reduction in specific gravity of the urine are present.

This clinical course may be divided into four phases, each designated by a characteristic physiologic aberration: (1) febrile, (2) hypotensive, (3) oliguric, and (4) diuretic.

In this Symposium, Lt. Robert J. Lukes describes the pathology of 39 fatal cases of this disease. There was almost constant occurrence of hemorrhage in the right atrium of the heart, of severe congestion, hemorrhage, and infarctlike necrosis in the renal medulla, and hemorrhage and necrosis in the anterior lobe of the pituitary gland, in association with the pattern of the vascular changes. All this supports the contention proposed in the Japanese literature and by Steer and Hüllinghorst that capillary damage is the basic process. Retroperitoneal edema, observed only once in secondary shock, is the striking pathologic feature when the patient dies during shock in early phases of the disease. The abrupt increase in incidence of pulmonary edema in the oliguric phase, particularly after the eighth day of the disease when retroperitoneal edema is rare, supports the clinically suspected role of redistribution of fluid and electrolytes with resorption of the abnormal interstitial fluid.

The frequent coexistence of pulmonary edema and bronchopneumonia in the oliguric and diuretic groups and the high incidence of pulmonary abscess formation support the concept of Moon that pulmonary edema of the albuminous type is conducive to the development of pulmonary infections.

The presence of necrosis of the anterior lobe of the pituitary gland in cases suggests that shock is not the only major factor in the pathogenesis of pituitary necrosis in hemorrhagic disease. Anoxemia is also an important factor, and is probably the major cause of necrosis in the absence of shock.

Studies of the coagulation mechanism in epidemic hemorrhagic fever reveal abnormalities in prothrombin activity, clotting time, and platelet count. Persistence of thrombocytopenia, which develops early in the disease, through the oliguric-hypertension phase, would appear to be causatively related to the bleeding phenomenon observed. Occasional marked deficiencies in plasma coagulation factors are found in seriously ill patients and may contribute to clinically significant bleeding. This plasma coagulation defect is similar to that observed in acute renal insufficiency and has not been clearly defined.

Studies by Giles and Langdon in this report suggest that some mechanism other than decrease in total blood volume is a primary cause of shock in

²Am. J. Med., May, 1954.

hemorrhagic fever. Although most patients showed normal red cell volumes during the febrile and shock phases of the disease, two showed a significant decrease during severe shock, and many others have decreases in other phases.

Studies by Froeb and McDowell in this report in the *American Journal of Medicine* on renal function in hemorrhagic fever show that the ability to form urine of high specific gravity may persist after the initial decrease in C_{IN} and C_{PAH} but is subsequently lost. The clearance returns to normal before the concentrating ability.

The following electrolyte abnormalities were observed during the course of hemorrhagic fever: (1) During the oliguric phase, hyponatremia, hyperkalemia, hypocalcemia, and retention of anions were common. However, serious hyperkalemia was rarely encountered and acidosis was not severe. (2) During diuresis, hyponatremia occasionally resulted from a "salt-losing" necropathy but more often was due to unknown causes. The hyperkalemia frequently increased during the early diuresis but at this time was not dangerous. Potassium deficiency, associated with the usual symptoms and signs of hypokalemia, sometimes occurred even though hypokalemia was not present. Hunter thus describes electrolyte abnormalities in hemorrhagic fever.

SUMMARY OF THE CHANGES IN THE BLOOD PICTURE

The following summary offers to the reader a recapitulation of the changes in the Schilling differential count seen in various pathologic conditions.*

I. Leukocytes With Increase in Basophiles.

1. Myelocytic leukemia.
2. Polycythemia vera.
3. Serum injection.
4. Hemophilia.
5. Convalescence from beriberi.
6. After multiple blood transfusions
7. In many conditions customarily accompanied by eosinophilia

II. Eosinophilia With Increased White Count.

Note: It is a biologic rule that severe irritations do not cause weaker or paradoxical reactions; that is, the same processes which in moderate degrees may produce eosinophilia, in greater degrees cause either hypereosinophilia or aneosinophilia.

1. Exudative processes: bronchial asthma, exudative diathesis and exudative intestinal catarrh of children, colitis membranacea, Quincke's edema, etc.
2. Anaphylaxis and anaphylactoid conditions: serum disease, hay fever, urticaria, migraine, idiosyncrasies, etc., irritations of vagus nerve.
3. All diseases due to worms wherever located. (Eosinophilia may dwindle to aneosinophilia [insufficiency] because of overinfestation.)

Trichinosis, schistosomiasis hepatica, ancylostomiasis, bilharziasis, filariasis, *Diphyllbothrium latum* infestation, echinococci, and intermittently with all intestinal parasites.

4. Skin diseases: psoriasis, pemphigus, urticaria, eczema, herpes zoster, impetigo contagiosa, some dermatitides, prurigo hebrae, pre-mykotic exanthema, mycosis fungoides, purpura.
5. Scarlet fever beginning on the third day of the eruption.
6. Gonorrhea, especially in females.

*Some of the hemograms given here are from Schilling: *The Blood Picture* (Translator, Gradwohl), The C. V. Mosby Co.

7. Tumors, occasionally, especially those of the lungs and peritoneum; rectal carcinoma, especially in serous metastases.
8. Nephrosis or nephritis occasionally (slight affections).
9. Muscular rheumatism (Bittorf).
10. Leukemia. This serves to differentiate leukemia from leukemoid pictures.
11. Pernicious anemia in the beginning, during remissions, under liver therapy.
12. Convalescence from infections (good sign).

III. Decrease or Absence of Eosinophiles.

THIS IS CONSIDERED AN UNFAVORABLE SYMPTOM.

1. Overirritation of eosinophilic processes, particularly in severe affections.
 - a. Due to worms.
 - b. Height of serum disease.
 - c. Pernicious anemia in severe stages.

Examples of Eosinophilia

	LEUKO-CYTES	BAS.	EOS.	MYEL.	JUV.	STAB.	SEG.	LYMPH.	MONO.	REMARKS
Bronchial asthma	14,000	1	10	—	—	3	40	43	3

Amebic dysentery	6,500	1	5	—	—	6	56	31	1	Amebae in the stools

Course of Eosinophiles in Infection

	LEUKOCYTES	BAS.	EOS.	MYEL.	JUV.	STAB.	SEG.	LYMPH.	MONO.
Lobar pneumonia	12,000	—	—	—	4	32	51 $\frac{1}{2}$	11 $\frac{1}{2}$	1
	8,200	—	(+)*	—	3	22	63	10 $\frac{1}{2}$	1 $\frac{1}{2}$
	8,100	—	3 $\frac{1}{2}$	—	1 $\frac{1}{2}$	21	44 $\frac{1}{2}$	23 $\frac{1}{2}$	6
	6,900	$\frac{1}{2}$	4	—	$\frac{1}{2}$	8	50	22	5

*Present in the thick drop.

- d. Malignant granuloma when severe.
- e. Acute leukemias, severe stages.
- f. Aleukemia, severe stages.
- g. Agranulocytosis, severe stages.
2. Acute stages of infections and most infectious diseases with the exception of gonorrhea and scarlet fever: particularly typhoid fever, pneumonia, diphtheria, bacillary dysentery, relapsing fever, measles.
3. Protozoal diseases during attacks.
4. Uremia and other intoxications.
5. Marked drop (50%) following administration of ACTH or cortisone.

IV. Normal Total Neutrophiles and Normal White Blood Count.

- 1. Normal individuals in the morning after a night's fast.
- 2. Diseases that very rarely influence neutrophiles.

V. Normal Total Neutrophiles and Low White Blood Count.

- 1. Severe pernicious anemia. (This usually shows neutropenia.)
- 2. Severe aplastic anemia. (This usually shows neutropenia.)
- 3. Osteoscleroses and diseases with reduction of bone marrow.

VI. Neutrophilia Without Shift But With Increased White Blood Count.

- 1. During digestion.
- 2. Muscular activity.
- 3. Spasmodic conditions.
- 4. After hemorrhages.
- 5. Polycythemia (at times a slight shift).
- 6. Very superficial or benign infections.
- 7. Simple intestinal catarrh.
- 8. Nephritides.
- 9. Abortive cases of infectious disease.
- 10. Polyarthrititis acuta. (Often shows a right shift.) (An acute infection without a left shift.)
- 11. Tetanus.
- 12. Struma.
- 13. Uncomplicated, malignant tumors.
- 14. After sodium chloride infusions, temporarily.
- 15. After certain medicaments.
- 16. During violent internal or external hemorrhages.

VII. Neutrophilia With Slight Stab Shift With High Normal or Increased White Blood Count.

- 1. Mild cases of acute infections and protozoal diseases: anginas, catarrhs, malaria during attacks.
- 2. Severe diseases of the digestive system: intestinal catarrhs, liver diseases, including jaundice, where the epithelia are alone involved.
- 3. Superficial, benign, or encapsulated infections:
 - a. After operations.
 - b. After incision of abscesses.
 - c. Suppurative wounds without general involvement.
 - d. Slight catarrhal appendicitis.
 - e. Open suppurations of eyes, ears, pharynx.
 - f. Appendicitis, gynecologic, and liver pus collections, entirely encapsulated.
 - g. Chronic diseases with neutrophilic irritation (septicemias and endocarditis).
 - h. Broken down ulcerative tumors.
 - i. Mild active tuberculosis.
 - j. Tuberculous abscess formation.

THESE SLIGHT SHIFTS ARE IMPORTANT FOR THE FOLLOWING REASONS:

- 1. To determine infectious processes.
- 2. To estimate the latent continuance of apparently healed infections, or the danger of relapse.
- 3. To outline as relatively harmless acute illnesses or exacerbations of severe conditions which have been reactivated.

Examples of Neutrophilia Without a Shift

	LEUKOCYTES	BAS.	EOS.	MYEL.	JUV.	STAB.	SEG.	LYMPH.	MONO.
Nephritis	18,000	—	2	—	—	4	76	13	5
Polyarthrititis acuta	26,750	—	—	—	—	3	85	10	2

Examples of Neutrophilia With Simple "Stab" Shift

	LEUKO-CYTES	BAS.	EOS.	MYEL.	JUV.	STAB.	SEG.	LYMPH.	MONO.	
Catarrhal jaundice	6,500	1	4½	—	½	9½	59½	17	8	Large wound
Burn	23,000	—	—	—	—	10	66	18	6	
Encapsulated abscess of kidney	9,300	—	½	—	—	11½	63½	20½	4	
Benign appendicitis	7,500	1	4	—	—	7	53	27	8	
Tubercular pleuritis	7,050	—	2	—	—	6	72	14	6	

VIII. Neutrophilia With Regenerative Shift and Increased White Blood Count.

1. Very violent exercise (marathon races).
2. Diabetic coma.
3. Pregnancy.
4. Severe cases of many acute infectious diseases: pneumonia, senile pneumonia, diphtheria, scarlet fever, cholera, bacterial dysentery, erysipelas, meningitis epidemica, typhus, variola.
5. Acute protozoal disease during attacks.
6. All acute and progressive internal infections: beginning empyema, newly formed abscess, appendicitis destructiva et perforata, peritonitis, purulent inflammation of bile ducts and urinary passages, pus infection of bone marrow, encapsulated malignant pustular affections of ears, eyes, and pharyngeal region, fresh cerebral suppurations, gynecologic processes, eclampsia, puerperal fever, severe intoxications due to bacterial poisons, heavy metals (lead, sublimate, etc.), coal gas, Lysol, phenylhydrazine.
7. Subsequent effects of leukopenic infection.
8. Acute exacerbations of chronic infections: tuberculosis, and endocarditis.
9. Transitions of leukopenic infection into one with severe regenerative complication: grippe with pneumonia.

IX. Neutrophilia With Hyperregenerative Shift With Decreasing or Low White Blood Count and Absolute Aneosinophilia.

THIS IS USUALLY AN AGONAL SYMPTOM OF VERY SERIOUS SIGNIFICANCE

- 1. Very severe infections.
- 2. Perforation peritonitis.
- 3. Croupous pneumonia.
- 4. Malaria comatosa.
- 5. Fatal blackwater fever.

X. Liberation Leukocytosis (with involvement of erythrocytes).

- 1. Complicated bone fractures.
- 2. Metastases of tumors.
- 3. Lymphogranulomata.
- 4. After intravenous injections and transfusions with bad reaction.
- 5. Blood crises, particularly in pernicious anemia, hemolysis, and blackwater fever.
- 6. Nonleukemic myelosis (aleukemic myelosis).
- 7. Marble disease (Albers-Schoenberg's disease).
- 8. Simple myelogenous metaplasia of the spleen.

XI. Persisting Leukemoid Leukocytosis.

- 1. Persisting direct irritation of bone marrow:
 - a. Carcinosis.
 - b. Malignant granuloses.
 - c. Polycythemia vera with hyperplasia of erythropoiesis.
- 2. Severe anemias complicated with infection.
- 3. Doubtful acute myelocytic leukemia.
- 4. Improved stages of agranulocytosis during cure (penicillin).

Examples of Neutrophilia, Leukocytosis, and Hyperregenerative Shift

	LEUKOCYTES	BAS.	EOS.	MYEL.	JUV.	STAB.	SEG.	LYMPH.	MONO.	REMARKS
Empyema of gall-bladder	Very high	—	(+)	±	15	34	34	8	9	
Eclampsia	Very high	—	(+)	1	29	20	34	5	11	
Mercuric chloride poisoning	27,000	—	—	1	9	20 $\frac{1}{2}$	59	5 $\frac{1}{2}$	5	3 hours after taking tablets
Lysol poisoning:

XII. Neutrophilia With Degenerative Shift With High Normal White Blood Count.

1. Mixed cases (typhoid with sepsis; tuberculosis with secondary infection).
2. Chronic or less virulent infections (hepatic abscess, recurrence, endocarditis).

XIII. Neutropenia With Low White Blood Count and Marked Stab Shift.

1. Kala-azar.
2. Other protozoal diseases *after* attacks.
3. During uncomplicated typhoid and paratyphoid fever.
4. Parotitis epidemica, in severe cases.
5. Pappataci fever.
6. Brucellosis (this sometimes shows neutrophilia).
7. Grippe.
8. Dengue.
9. Not infrequently in tuberculosis.

XIV. Neutropenia With Low White Blood Count and No Known Shift.

1. Pellagra.
2. Yellow fever.
3. Spotted fever.
4. Kedani or tsutsugamushi (scrub typhus).
5. Chicken pox.
6. Poliomyelitis acuta.
7. Ophthalmia sympathica.
8. Pernicious anemia.

XV. Neutropenia With Low Total White Blood Count and No Shift, Often Total Absence of Neutrophiles.

1. Agranulocytosis.
2. Aplastic anemia.
3. Experimentally in anaphylaxis.

XVI. Neutropenia With Shift to the Right.

THESE PICTURES SHOW ABSENCE OR DIMINUTION OF STABS AND NUMEROUS HIGHLY SEGMENTED NEUTROPHILES WITH SIX OR MORE SEGMENTS AND DENSE GRANULES, AND A TENDENCY TO LARGE, OVOID CELLS.

1. Pernicious anemia.
2. Very severe anemias with pernicious blood picture.

- a. Syphilis.
- b. Pernicious anemia of pregnancy.
- c. Sprue.
- d. Carcinoma of the stomach.
- e. *Diphyllobothrium latum* infestation.
- f. Less frequently in other worm diseases.
- g. Occasionally in malaria and septic processes.
- h. Less marked in avitaminoses (pellagra).
- i. Conditions due to insufficient food.
- j. Cirrhosis of the liver.

XVII. Normal Lymphocytes and Normal White Blood Count.

- 1. In normal individuals after a night's fast.
- 2. Diseases not influencing the lymphocytic picture.

- 3. Physiologic leukocytoses and benign infectious leukocytoses of long duration, as a favorable symptom.
- 4. In association with aplastic or aregenerative anemias.

XVIII. Lymphocytosis With Increased Total White Count.

- 1. Constitutional in some individuals.
- 2. First phase of physiologic or very slight irritation leukocytosis, during exercise, digestion, etc.
- 3. Epilepsy during the attacks.
- 4. Lymphocytosis of crying nursing infants.
- 5. Parotitis epidemica during course of mild cases.

6. Pertussis.
7. Uncomplicated benign (afebrile) tuberculosis and syphilitic processes.
8. After certain medicaments; as Adrenalin.
9. Lymphocytic leukemia.
- 10..Acute infectious lymphocytosis.
11. Infectious mononucleosis.

XIX. Lymphocytosis With Normal or Low White Blood Count.

1. All conditions with neutropenia as an associated condition.
2. Lymphocytic aleukemia.
3. Granulomatoses, especially in stages without fever.
4. Neurasthenia and vagotonia (constitutional).
5. Basedow's disease.
6. Acromegaly.
7. Myxedema.
8. Aregenerative anemias, particularly pernicious anemia.
9. Most protozoal diseases during recurrence.
10. During attacks or intervals of conditions caused by viruses.
11. Beriberi.
12. Pure scurvy.
13. Metabolic diseases in chronic stages, similar to conditions of hunger.
14. Achylia gastrica simplex.
15. Uncomplicated benign tuberculosis.
16. Uncomplicated syphilis.
17. Continued roentgen exposure.
18. After infections, as a phase of recovery.
19. After vaccinations (typhoid, cholera, dysentery, tuberculin, etc.)

XX. Lymphocytosis With Marked Low Total White Blood Count.

1. Grippe.
2. Pappataci fever.
3. Typhoid fever.
4. Brucellosis.
5. Kala-azar.
6. Agranulocytosis.
7. Aleukia.
8. Aplastic anemia.
9. Pernicious anemia.

XXI. Lymphocytopenia With Increased White Blood Count.

1. Relative in myelocytic leukemia.
2. Accompanying symptom in conditions with neutrophilia.
3. Severe infections.

XXII. Lymphocytopenia With Normal, Subnormal, or Very Low White Blood Counts.

- 1. Marked in measles shortly before and after the outbreak of the exanthem.
- 2. Sometimes in yellow fever and typhus.
- 3. Malignant attacks of certain diseases with lymphocytic changes (typhoid fever).
- 4. Paroxysmal hemoglobinuria during attacks.

XXIII. Monocytosis With Increased White Blood Count.

- 1. In health or slight illnesses if the first drop of blood from the ear is used without cleaning, and rubbing the ear.
- 2. Endocarditis ulcerosa (cells endothelioid and vacuolated).
- 3. Variola (with the "gay" blood picture).
- 4. Typhus in later stages.
- 5. Measles and German measles.
- 6. Varicella, less marked.
- 7. Slight in scarlet fever.
- 8. Less marked in parotitis epidemica, mild cases.
- 9. Less marked in acute syphilitic and tuberculosis processes.
- 10. Infections and infectious diseases as a secondary finding with good prognosis.
- 11. Monocytic leukemia.
- 12. Malignant endocarditis lenta ulcerosa (macrophages).

XXIV. Monocytosis With Low Normal to High Normal Counts of White Blood Cells.

- 1. Chronic vascular diseases, such as severe arteriosclerosis, in recovery, especially near the crisis.
- 2. Chronic syphilis and tuberculosis.
- 3. Slight in malignant tumors.
- 4. Acute protozoal diseases during the attacks (malaria, trypanosomiasis).
- 5. Severe cases of parotitis epidemica.
- 6. Basedow fruste.
- 7. Helminthiasis.
- 8. Hyporegenerative septic processes as a secondary finding.
- 9. Agranulocytosis.
- 10. Banti's symptom complex.
- 11. Measles.
- 12. Yellow fever.
- 13. Dengue fever.
- 14. Spotted fever.
- 15. Ophthalmia sympathica.
- 16. Poliomyelitis.
- 17. Pellagra.

XXV. Decrease or Absence of Monocytes.

1. Very severe infections as a very unfavorable symptom.
2. Myelocytic and lymphocytic leukemias.

LEUKEMIA

TABLE 65.—LEUKEMIAS AND LYMPHOMAS*

TERM TO BE USED	TERMS TO BE AVOIDED
<i>Leukemia and Lymphoma</i> , generally, <i>Leukemia</i>	Leukosis, leukanemia, leukosarcoma, leukocythemia
Type unclassified	
Lymphocytic	Lymphoblastic leukemia or blast cell leukemia
Acute	Lymphadenosis, lymphocythemia, lymphatic, lymphoid or lymphogenous leukemia
Leukemic	
Subleukemic	
Aleukemic	
Subacute	
Leukemic	
Subleukemic	
Aleukemic	
Chronic	
Leukemic	
Subleukemic	
Aleukemic	
Granulocytic	Myeloblastic leukemia
Neutrophilic	Myeloid, myelogenous, myelocytic leukemia, mye- losis, myelemia, myelocythemia
Eosinophilic	
Basophilic	
Monocytic	Reticuloendotheliosis, histiomonocytic, Schilling type, myelomonocytic, or Naegeli type leukemia
Plasmocytic	
Megakaryocytic	
<i>Lymphoma</i>	Lymphoblastoma, lymphocytoma, malignant lym- phadenoma
Type unclassified	
Lymphocytic sarcoma	Lymphosarcoma
Reticulum cell sarcoma	Reticulosarcoma
Follicular lymphoma	Giant follicular lymphoma, giant follicular lympho- blastoma, lymphoid follicular reticulocytosis, Brill-Symmer disease
Hodgkin's disease, unspecified	Hodgkin's lymphoma, Hodgkin's lymphoblastoma, Hodgkin's pseudoleukemia lymphogranulomatosis
Hodgkin's paraganuloma	
Hodgkin's granuloma	
Hodgkin's sarcoma	
Mycosis fungoides	
Spiegler-Fendt sarcoid	
Plasmocytic myeloma	Multiple myeloma, plasma cell myeloma, plasmoc- ytoma, myelocytoma, Kahler's disease
Erythrocytic sarcoma	Erythroblastoma
Mixed types

Leukemia is not a disease of a single species of cells in the blood or of a single hematopoietic organ. Rather it is a general disease of the systems that manufacture the leukocytes and also of the small cellular centers outside the ordinary blood-manufacturing centers. It is characterized by a more or less atypical hyperplastic new formation of white cells. These cases are eminently malignant and, therefore, are to be differentiated distinctly from simple metaplasia and from the leukocytoses. Leukemia is an extreme leukocytosis superimposed upon a specific irritation.

The historical development of leukemia might be said to begin with a description of the disease by Virchow in the eighteen fifties, when he outlined the "lienal" and "lymphatic" forms of leukemia. Between 1875 and 1877 Virchow differentiated leukemic cell increase from the leukocytoses due to pus formation. With the advent of selective stains into hematology there began recognition of the difference between the lymphocytic and the myelocytic leukemias. Then came Naegeli's characterization of the myeloblast which gave this dualistic conception of the disease a firm basis. With the final appearance of the oxydase reaction, it was possible to histologically differentiate myelocytic from lymphocytic cells.

Fig. 199.—Myelocytic leukemia, blood film, showing crowding of cells, and an increase in large myelocytes and myeloblasts. ($\times 950$.)

The essential features of leukemias are seen in blood pictures. There is not only an increase in the total count of the leukocytes, but a qualitative cellular change as well. The disease is usually characterized by a prolonged incubation period, with general symptoms suggestive of climacteric or endocrine disturbances: lethargy, fatigue, rheumatoid pains—all symptoms that are not often taken to the physician for review. Frequently the palpable spleen or enlargement of glands is the first symptom noted by a physician of the existence of a leukemia. In advanced cases, there is pressure on the stomach, sometimes with vomiting, stinging pain in the splenic region, dyspnea, insomnia, perspiration, eventually subicteric color.

The etiology of leukemia is not known. Possible etiological causes are: (a) *Specific infection*. This has been often discussed but never proved. (b) *Generalized infectious irritation*. The anamnesis of a number of leukemia cases shows a series of infectious diseases, which suggests the possibility of an abnormal form of reaction to repeated infections. (c) There is a *tumor theory* due to the fact that there is a decided analogy to tumor processes in leukemia.

Ellermann has described a chicken-leukemia, which may be transferred by means of a filtrable virus, but which alternately shows myelocytic, lymphocytic, and erythropoietic hyperplasias. Snijders¹ reported in 1926 a large cellular leukemia of a guinea pig. One hundred forty-eight other guinea pigs which were inoculated with living cells from the first pig developed leukemia; some showed tumorlike infiltrations, some highly tumorous "leukosarcomatosis," etc. The proliferating cells all seemed to originate from the transplanted foreign cells. This may explain the development of generalized processes from a local tumorous tissue, and would also explain old descriptions of leukemias after crushing of the spleen, bone fracture, contusions, etc. (d) There is a theory of *disturbed correlation*. Ziegler is said to have experimentally produced genuine leukemias by destroying one blood system, followed by a degeneration of the other system. (e) There is a *constitutional* theory, but the literature on heredity in leukemias is entirely inadequate.

Fig. 200.—Blood film, leukopoesis, showing a large number of myelocytes and juveniles. (×950.)

Types of Leukemia

There are two main types of leukemia, acute and chronic. It is customary to classify the leukemias further on the basis of the predominating cell type into three classes: (1) myelocytic; (2) lymphocytic; and (3) monocytic. Other forms of leukemia have also been described: plasma cell leukemia, basophilic (?) leukemia, atypical leukemia, and leukemoid blood pictures.

The Chronic Leukemias

Chronic Myelocytic Leukemia.—Chronic myelocytic leukemia is characterized by highly active hyperplasia of the bone marrow which floods the blood stream with all the varieties of mature and immature leukocytes of marrow origin. In this disease there are a great many white cells, chiefly the immature

forms of the granular leukocytes, together with a progressive anemia showing many varieties of nucleated red cells. The name "leukemia" was given by Virchow to this disease because of the appearance of the blood at autopsy, namely, whitish, but this appearance is never seen during life.

The total white count is usually about 100,000 per cubic millimeter, but it may go as high as 1,000,000 per cubic millimeter. When the count is very high, it is necessary to use the red blood counting pipette in making the white count. (See page 577.)

The differential count of leukocytes varies in different patients. The neutrophile is the predominant cell in some cases, but this is not always true. Eosinophilic leukocytes are constantly increased in actual numbers and percentage. Basophiles may be increased up to 10 to 15 per cent of a high total count. Myelocytes are always present; usually they are numerous, sometimes forming one-half of the total white cells in the blood picture. The greater the blood count, the greater the number of myelocytes, especially in the later stages of the disease. Most of the myelocytes are neutrophilic, but there usually are eosinophilic and basophilic myelocytes as well. About 3 to 5 per cent of the cells in the differential count are myeloblasts with a few promyelocytes. There are usually less than 5 per cent of lymphocytes in the total count. There may be an occasional monocyte. The myelocytes are often atypical, varying in size and number of granules. Often the neutrophilic myelocytes retain the blue-staining cytoplasm which designates younger cells. There are many intermediate forms between the myelocyte and the "stabs" in this disease. These intermediate forms are called "juveniles" but many of them are atypical. With the oxydase stain, one can easily recognize just how many cells in the blood film are myeloid in origin.

The white cell count in the terminal stage may approach a normal figure due to the complete asphyxiation of the bone marrow function. In the terminal stage increasing immaturity in cell forms is seen. So many myeloblasts are seen that the picture suggests an acute myeloblastic leukemia.

It must be remembered that transitions from a chronic myelocytic blood picture to an acute myeloblastic one will occur and are connected with unfavorable changes in the course of the disease. A relapse or a terminal condition in chronic leukemia is usually attended with an acute blood picture.

Remissions are spontaneous. Apparent recoveries take place in leukemia. These remissions seem to date from the appearance of some intercurrent infection such as pneumonia, erysipelas, or pus infection; sometimes, tuberculosis. It seems likely that in the presence of a stimulus to leukocytosis the marrow reverts for a time to a normal and orderly leukopoiesis, returning later, of course, to its leukemic tendencies. These remissions sometimes last several months, but one must not be deluded into the thought during this period that the patient has been cured. Total count may drop from several hundred thousand to a normal figure following an acute infection, but sooner or later, the count insidiously begins to rise. Later on, with the end of the remission, the total count rises and the differential count becomes as characteristic as it was before. The red cell count, however, does not ever become normal during

a remission. Von Koranyi first used benzol in the treatment of leukemia with reduction of the white cells from 170,000 per cu.mm. to 8,000 per cu.mm. These apparently favorable results do not last long, so that the benzol treatment has fallen into disuse. Irradiation treatment of the long bones in the treatment of this disease is more popular today since it can be better controlled and produces less anemia. Refer to pages 888 ff. for the treatment of leukemia.

Red Cells and Hemoglobin in Leukemia.—Naegeli states that polycythemia is always present in mild cases of leukemia, but this is only for a very brief period. Anemia appears with hemoglobin falling to 60 per cent and red cells going down to 3,000,000. Color index remains around 1.0. As the disease progresses, the anemia becomes more severe. There is an increase in reticulocytes and many normoblasts appear in the picture. Typical megaloblasts are seen. Karyokinetic figures are found in the nuclei of these erythroblasts.

In the terminal stage of chronic myelocytic leukemia, the anemia becomes more marked as a result of which the patient usually dies. The picture at this point is very much like a true pernicious anemia.

Fig. 201.—Lymphocytic leukemia, blood film, showing crowding of lymphocytes. ($\times 950$.)

Blood Platelets.—Blood platelets are increased to high figures. Minot and Buckman¹ reported as high as 2,000,000 blood platelets per cu.mm. The blood platelet count drops in the terminal stage.

Differential Diagnosis Between Chronic Myelocytic and Chronic Lymphocytic Leukemia.—The differential diagnosis between chronic myelocytic and chronic lymphocytic leukemia can be made on the basis of the generally larger spleen and by the absence of marked lymph node enlargement in chronic myelocytic leukemia. The *blood examination* is, of course, the best method of making the differential diagnosis. The differential count shows an increase in the neutrophilic elements in chronic myelocytic leukemia, whereas in lymphocytic leukemia, the increase is in the lymphocytes. The lymphocytes are relatively decreased in chronic myelocytic leukemia.

¹Minot, G. R., and Buckman, T. E.: *Am. J. M. Sc.* 169: 477, 1925.

Making a Differential Count of Blood in Myelocytic Leukemia

To make a differential count of blood in myelocytic leukemia, construct a recording sheet as shown on page 852 and proceed to count 500 leukocytes.

In reporting the count, divide the total results by 5 to convert to per cent, or the number of different types of cells in 100 leukocytes. Forms of reports vary in different institutions, but where no laboratory form is at hand, the following is suggested:

	M'blast	Pro.	B. Myel.	Baso.	Eo. Myel.	Eo. Juv.	Eo. St.
	10.2	6.2	0.6	1.4	2.2	0.4	0.6

Eo.	Neut. Myel.	Neut. Juv.	Neut. Stab.	Neut. Seg.	Lymph.	Monó.	Other Cells
3.8	16	12	8.6	36	0.8	1.0	0.2

For every 100 leukocytes counted there were:

0.8 P. megaloblasts, one with karyorrhesis

1.6 P. macroblasts, two with karyorrhesis

8.0 P. normoblasts, three with karyorrhesis

One erythroblast in mitosis found in the slide. Marked polychromasia, slight anisocytosis, enlarged blood platelets.

Chronic Lymphocytic Leukemia is a disease of middle and later life, rare under age 20 and most common after 50. The pathology is in the lymphatic tissues. The spleen is not usually as enlarged as in myelocytic leukemia. The spleen is engorged with lymphocytes and often shows areas of infarction. The bone marrow shows replacement of fat and replacement of normal red cell and myeloid cell tissues by lymphocytic infiltration. The lymph nodes of the entire body are enlarged, including not only the superficial glands of the neck, axillae, groins, etc., but the lymphoid follicles of the nasopharynx, tonsils, tongue, and gastrointestinal tract as well. The retroperitoneal and mediastinal nodes are often enlarged and cause symptoms by pressure. Cellular hyperplasia is shown throughout the body by the vast collections of large and small lymphocytes. There is an anemia present due to the crowding out of erythropoietic tissue by the lymphocytes. There is relative neutropenia.

The white count varies from 50,000 to 1,000,000 with an average of 100,000 per cu.mm. Eighty per cent or more of the cells in the differential count are lymphocytes of approximately the same size.* The remaining cells are neutrophils, including myelocytes, with a few eosinophiles, basophiles, or monocytes. Lymphoblasts and abnormal lymphocytic forms are seen in acute relapses. The red cell changes are those commonly seen in anemias connected with myelogenous or lymphatic dyscrasias (page 850). The blood platelets are reduced and there is a slight prolongation of bleeding time.

Lymphocytic leukemia is likely to show a transition of the blood picture to aleukemic state or even to acute state just as is seen in myelocytic leukemia. This occurs spontaneously or during the course of treatment or because of the onset of an intercurrent infection.

The Acute Leukemias

The Acute Leukemias.—(Myelocytic, Lymphocytic, Monocytic).—Friedreich¹ reported a case of leukemia with an acute course. Ebstein² in 1889

*The "monotonous" blood picture.

¹Friedreich, N.: Arch. f. path. Anat. 12: 37, 1857.

²Ebstein, W.: Arch. f. klin. Med. 44: 343, 1889.

described the clinical picture of acute leukemia. Fraenkel³ in 1895 called attention to changes in the cells in the blood and claimed that all acute leukemias were of lymphatic origin because of the similarity of the cells to lymphocytes. Naegeli⁴ in 1900 first described the myeloblast, furnishing the first data on which to classify two types of leukemia, myelocytic and lymphocytic. It remained for Schilling and Reschad⁵ in 1913 to describe their classical case of acute monocytic leukemia. This is considered the first case of this type reported, or the first case of reticuloendotheliosis, as some prefer to call it. Up to the time of Clough's report in 1932⁶ but twenty-three cases had been cited. In February, 1934, Forkner⁷ reported that during the past two years sixteen more cases of acute leukemia had been studied at the Thornlike Laboratory of the Boston City Hospital; these sixteen cases were divided into the three main types, myelocytic, lymphocytic, and monocytic (six of the latter). Post-mortem examinations were made in four of the six cases of monocytic leukemia. One case of myelocytic and one case of acute lymphocytic leukemia were included with autopsy findings.

Fig. 202.—Monocytosis, blood film, showing large number of monocytes. (X950.)

Forkner called attention to certain clinical differences between acute monocytic and other forms of acute leukemia. He insisted that the clinical picture of diffuse, marked swelling of the mucous membranes, particularly of the gingivae usually with ulceration and necrosis, is characteristic of acute monocytic leukemia and is usually absent in acute leukemia of the other types. There was a diffuse cellulitis around the lesions of the mucosa, causing swelling and pain with signs of acute inflammation extending into the deeper tissues of the face. It was for this reason *that all these patients with monocytic*

leukemia reported by Forkner consulted a dentist early in the course of their illness. While acute lymphocytic and myelocytic leukemia often have mouth lesions, they are different, consisting of hemorrhages and slight infection, not necrosis. This fact stands out prominently in the twenty-three cases reported by Clough⁸: eighteen had marked stomatitis or pharyngitis, abscesses of the alveoli, and four had swelling of the neck. Forkner studied the case histories of eight additional cases which were not accepted by Clough. Three cases reported by Ewald, Frehse and Hennig⁹ in 1922, one additional case by Bingel¹⁰ in 1916, one case by Dias¹¹ in 1930, one case by Hittmair¹² in 1930, and two cases by Asselstine¹³ in 1932 showed lesions of the mouth similar to those seen in the other eighteen cases tabulated by Clough.

There are other physical signs which serve to differentiate these cases. The spleen is somewhat enlarged but is not palpable in acute myelocytic leukemia but in the acute lymphocytic type it is palpable 2 to 3 cm. below the costal margin. The spleen in acute monocytic leukemia according to Clough was palpable in sixteen of the twenty-three cases recorded by him. In Forkner's six cases the spleen was palpable from 1 to 4 cm. below the costal margin. The weights of the spleens in the four cases studied by him at autopsy were: 1,065; 606; 360; and 900 gm., respectively.

The size of the lymph nodes should be used as an aid in the diagnosis of the type of acute leukemia. Forkner claims that there is invariably an enlargement of the lymph nodes in acute lymphocytic leukemia, but it is not so marked as in chronic lymphocytic leukemia. The lymph nodes, particularly those in the neck, may be slightly or moderately enlarged in acute monocytic leukemia, but we never see the enlargement in this disease that occurs in the acute lymphocytic type. There is only a negligible enlargement in acute myelocytic leukemia.

This clinical and histologic differentiation of the three types may be seen by studying Table 67, arranged by Forkner.

The characteristics above set forth will help the differential diagnosis, in the absence of a clear-cut blood picture or histologic study of the tissues at autopsy.

Blood Picture.—There has existed considerable confusion as to the cytology found in these three types of acute leukemia. This is enhanced by the fact that as many as 85 per cent of the leukocytes in any case of acute leukemia are of a uniformly immature type, usually in the myeloblast, lymphoblast, or monoblast stage of development. Intermediate stages are few in number. There are, too, some immature types present other than those of the typical leukemia with which we are dealing. Sabin,¹⁴ Simpson,¹⁵ and others, however, have rediscovered a method of aiding in the recognition of these cells; namely, the supravital method. One must not forget, too, that the oxydase test, as

TABLE 67.—CLINICAL AND HISTOLOGIC DIFFERENTIATION OF THE THREE MAIN TYPES OF ACUTE LEUKEMIA

	ACUTE MYELOCYTIC LEUKEMIA	ACUTE LYMPHOCYTIC LEUKEMIC	ACUTE MONOCYTIC LEUKEMIA
Spleen	Usually not palpable	Almost invariably significantly enlarged	Palpable in about 70 per cent of cases
Lymph nodes	Usually slight or no enlargement	General enlargement of moderate or marked degree	Moderate in neck, but other lymph nodes very slightly enlarged, if at all
Liver	Usually palpable	Usually palpable from 1 to 4 cm. below costal margin	Usually palpable from 1 to 4 cm. below costal margin
Mucous membranes, particularly of mouth and pharynx	Petechiae, bleeding; often slight swelling of gingivae but rarely ulceration	Petechiae, bleeding; rarely ulceration	Petechiae, bleeding; usually marked, diffuse swelling of gingivae or pharynx with ulceration; often cellulitis with swelling and tenderness of face; marked fetor oris
Oxydase reaction	From few to many oxydase-positive cells, with from few to many coarse granules	All lymphoid cells oxydase-negative	
Histologic distinctions of type cells in blood and tissues	Dominant cells myelocytes "A" (Sabin) and myeloblasts; nuclei round or oval, usually with several nucleoli; cytoplasm deeply basophilic; myelocytes "B" (Sabin) present; Auer's bodies frequently present in few cells	Dominant cells lymphoblasts and young lymphocytes; nuclei round, oval or slightly indented, with few nucleoli usually present; relatively small amount of deeply basophilic, hyaline cytoplasm; mature lymphocytes present in fair number; occasional myelocytes. "C" (Sabin) and metamyelocytes present	Dominant cells monoblasts and premonocytes; nuclei usually elongated and folded, deeply indented or otherwise irregular in contour; nucleoli rarely present; cytoplasm relatively abundant, usually not deeply basophilic and not hyaline but slightly basophilic and "ground glass-like"; Auer's bodies may be present in few cells; mature monocytes present in significant and varying numbers; myelocytes "C" and metamyelocytes often present in small numbers
Other characteristics			

used by Schilling and his followers, is of paramount importance in this regard. Forkner, with illustrated charts of cells found in cases, called attention to some striking points of identification in regard to myeloblasts; the nuclei are round, indented or oval, and contain several nucleoli. The cytoplasm is basophilic and of uniform character. The cells in monocytic leukemic cases are more mature, possess nuclei of complicated characteristics, with very few nucleoli; their cytoplasm is relatively abundant, is basophilic, and contains dustlike granules (see description of monocytes, page 641).

Histologic Differentiation of the Acute Leukemias.—The oxydase test for blood cells is a method for the differentiation of the tissues at autopsy in all leukemias. This is helpful criterion for the pathologist. Cells infiltrating the

liver, kidney, etc., if oxydase-positive, point to the myelocytic character of the case. If oxydase-negative, it is a case of lymphocytic leukemia or lymphoblastoma. In monocytic leukemia, the oxydase reaction may be positive or negative. Forkner calls attention to certain definite means of distinguishing monocytic cells in paraffin sections. Under the oil immersion lens, they show characteristics that will distinguish them from myeloblasts or lymphoblasts. The nuclei even of promonocytes and of some monoblasts are irregular in shape, in the form of an irregular crescent or a broad elongated nucleus bent upon itself. The nucleus is bent on itself several times, giving the impression of lobulation. This point made by Forkner is very impressive, especially since he has so insistently called attention to the "lobulation" of the nuclei of monocytes. May it not be true that this is not a lobulation but a pseudolobulation, as pointed out by Forkner? Distinct separation of the lobules is not demonstrable, in contrast to the ease of so doing with respect to the segmented neutrophile. There are also many young monocytic cells, with simple round, oval, or slightly indented nuclei, but these cells exist as close companions of the cells with the more complicated nuclei as described. Furthermore, there are other characteristics which serve to distinguish the monocytic cells from the early lymphoid and myeloid elements. The nuclei of the monocytic series of cells rarely have demonstrable nucleoli, whereas these structures are very common in lymphoblasts and myeloblasts. The cytoplasm of promonocytes and monoblasts is, as a rule, more abundant and much less basophilic than that of either lymphoblasts or myeloblasts and frequently it is so faint, with hematoxylin, that the border of the cell is barely recognizable. This is in contrast with the moderate or very deep basophilia of early lymphoid and myeloid cells.

In reference to the terms, acute and chronic lymphocytic leukemia, Wiseman³ has introduced the thought that from a hematologic point of view responses of the lymphatic tissue vary to such a degree that the terms acute and chronic are inadequate to express this change. Neither do these terms take into account the important relationship of lymphosarcoma to leukemia. "Finally," he states, "there does not appear to be any justification for the term 'aleukemic lymphatic leukemia,' since there is no fundamental pathologic difference between cases presenting low and high total white blood cell counts." He showed records that indicated that lymphocytic leukemia may be a very benign disorder which does not materially shorten life or measurably diminish health. On the other hand, it may kill quickly. It is probable that there are many more cases in the former group than one would suspect since many are asymptomatic, do not show physical signs, and hence are not seen by the physician.

Monocytic Leukemia (Leukemic Reticuloendotheliosis).—This is a rather rapidly fatal disease showing increased numbers of monocytes in the blood stream and in other organs. It was first reported by Reschad and Schilling⁴ in 1913. Rosenthal⁵ reported the first case in America in 1921. A large number of cases has since been reported, 127 in all in the American literature up

³Wiseman, B. K.: *J. A. M. A.* **107**: 2016, 1936.

⁴Reschad, H., and Schilling, V.: *München. med. Wchnschr.* **60**: 1981, 1913.

⁵Rosenthal, N.: *M. Clin. North America* **4**: 1607, 1921.

to June, 1937, and 45 cases of this disease are on file in the Registry of Blood Diseases of the American Society of Clinical Pathologists. Osgood⁸ reported six cases and Rosenthal and Harris and Doan and Wiseman found reports of 532 cases of leukemia, from which statistics on the incidence of monocytic leukemia were calculated. It was estimated that 62.2 per cent were cases of myelocytic leukemia, 32.7 per cent were cases of lymphocytic leukemia, and 5.0 per cent were cases of monocytic leukemia.

In considering this disease, the two schools of thought relating to the origin of blood cells must be taken into account; one school, of which Naegeli is a proponent, denying the reticuloendothelial source of the monocytic cells, and the other, of which Schilling is the leading proponent, insisting that these cells originate from reticuloendothelial structures. It can no longer be denied that there are certain cases of monocytic leukemia which start out to all intents and purposes as myelocytic leukemia. These cases inevitably become cases of pure monocytic leukemia. Naegeli has claimed that monocytic leukemia is a temporary monocytic phase of myelocytic leukemia, and that the monocyte is a descendant of the myeloblast. He denied that monocytic leukemia is a distinct pathologic entity and cited cases which at one time exhibited the hematologic features of monocytic leukemia and in which the typical blood picture of myelocytic leukemia developed later. From such cases he claimed to trace intermediate stages between myeloblasts and monocytes. Merklen and Wolf,⁹ Gittins and Hawksley, Reich, and others have reported cases supporting Naegeli's views. On the other hand, Schilling and his followers have maintained that monocytic leukemia is a distinct pathologic entity in which there is monocytosis in the circulating blood and hyperplasia of the reticular tissue in the hemopoietic organs. Schilling maintains that this disease is separate from myelocytic and lymphocytic leukemia. Forkner¹⁰⁻¹² believes that monocytes and their precursors are not a part of the reticuloendothelial system and that there is no clear-cut evidence of any intimate relationship between monocytes and the reticuloendothelial system, if the latter was considered in its strict sense. He likewise claims that any relationship of monocytes to myeloblasts has never been proved and he does not believe that the type of leukemia ever changed, for example, from monocytic to myelocytic leukemia.

It is for the reason that undoubted cases of myelocytic leukemia changing to monocytic leukemia have been reported by reliable workers that it is necessary to divide monocytic leukemic cases into two types: the first type, the monocytic leukemia of the Schilling order; and, second, the monocytic leukemia of the Naegeli type.¹³

Monocytic Leukemia of the Schilling Type.—Monocytic leukemia may occur at any age, the youngest patient reported being 11 months old and the oldest 78 years. The clinical course runs about the same as the other acute

⁸Osgood, E. E.: *Arch. Int. Med.* 59: 931, 1937.

leukemias, lasting from two weeks to a few months. Infection of the mouth or throat and spontaneous purpura are commonly seen. Swelling of the gums is a constant feature and is more marked and constant than in other cases of acute leukemia. This swelling is associated with gangrenous stomatitis. There is enlargement of the spleen and lymph nodes. Enlargement of the liver is also common, having been observed in 66 per cent of the 90 cases in which a notation was made. Other clinical symptoms are pallor, weakness, and fever. There are also cutaneous lesions of two types: nodules in the skin which are firm and painless, which on histologic examination prove to consist largely of monocytes, promonocytes, monoblasts, and reticular tissue; and staphylococcic infection of the skin, with multiple boils and carbuncles.

Fig. 203.—Endocarditis, showing endothelioid monocytes. ($\times 950$.)

The Blood Picture.—The blood picture shows a marked or moderate decrease in red cells and hemoglobin. There is a definite increase in the white cell count. The average of the highest counts recorded in each case was 99,600. A few cases showed leukopenia. Differential count showed mature monocytic cells forming about 50 to 75 per cent of the total count. Sometimes the immediate precursors of the monocyte, including the histiocytes, are present. The cytoplasm resembles that of the mature monocyte, being blue gray and of ground-glass appearance, with typical fine monocytic granules which are first seen about the nucleus in the youngest cells. The nucleus is large, oval, bean-shaped, or even lobulated. The chromatin is arranged in a very fine spongelike meshwork which becomes coarser and skeinlike in more mature cells. While most of the observers report that the immature cells are oxydase-negative, Farley¹ and Lawrence² and his co-workers found the cells to be oxydase-positive.

¹Farley, D. J.: *M. Clin. North America* 13: 991, 1930.

²Lawrence, J. S.: *Folia haemat.* 44: 332, 1931.

Histologically, the architecture of the lymph nodes and spleen is obliterated by a marked proliferation of reticular cells. Periportal growth is seen in the liver, and proliferation of reticular cells is found in the kidneys, the serosal surfaces, and the perivascular stroma of nearly all the organs, especially the adrenal glands, thymus, pancreas, and gastrointestinal tract.

The bone marrow shows a preponderance of monocytic cells. These are monoblasts which are very large, from 15 to 30 microns in diameter. Chromatin structure of the nucleus is very fine, similar to that of the myeloblast but even more transparent. The nucleus is usually round or oval. The cytoplasm ranges from basophilic to deeply basophilic, and there is more in proportion to the size of the nucleus than in the myeloblast or the lymphoblast.

Fig. 204.—Blood film showing a phagocyte. ($\times 950$.)

As Osgood pointed out, monoblasts are difficult, sometimes impossible, to distinguish from myeloblasts or lymphoblasts. The chief difference is the more frequent occurrence of fine, diffuse azurophile granules in the cytoplasm of the monoblast, similar to those of the mature monocyte. Peroxidase stain does not assist in this differentiation, as all these cells may show a negative peroxidase reaction. Osgood, from his study of six cases and a review of the literature, definitely believes that the monocyte is developed from a cell which may be called the monoblast, similar in morphology to the myeloblast. This is very interesting in view of the fact that Forkner has listed nineteen different views as to the origin of the monocyte, which clearly shows the confusion that exists in regard to the origin of this cell. It is gratifying to know that a hematologist of Osgood's experience has so definitely accepted the entity of the monocyte as so determinedly maintained by Schilling and his followers all these years. Osgood has also commented upon the difficulty of distinguishing the blast cells from each other, namely, monoblasts, myeloblasts, lymphoblasts, and the plasmablasts. They are entities, of course, just as the megakaryoblast is, each of which can develop only into a mature cell of its own series. It

is to be hoped that cultures of marrow, which have been so well carried out by Osgood and Brownlee and Osgood and Muscovitz, will some day definitely settle this point. The type of cell which is found in the peripheral blood has been described by the various contributors to the literature of medicine on this question. Unfortunately, many of them have failed to differentiate between the mature and the immature cells of the monocytic variety in the circulating blood. Those who have been able to make this distinction have commented, of course, upon the finding in the peripheral blood not only of monocytes but of promonocytes, which are a more immature form of this cell.

Monocytic Leukemia of the Naegeli Type.—A report by Hall and Watkins¹ may be taken as an example of the monocytic leukemia of the Naegeli type, that is, beginning as myelocytic leukemia and changing to monocytic leukemia. This is similar to a case reported by Craciuneanu and Calalb² in 1931, which was as follows:

“The patient, a white woman aged 40 years, complained of fatigue, headache, insomnia, palpitation, and tumor in the left upper quadrant of the abdomen. These symptoms had developed three months previously. Later, she had experienced anorexia, vomiting, pallor, and weakness.

“Physical examination disclosed emaciation, pallor, a slight degree of adenopathy in the left cervical region, hepatomegaly, and a tremendously enlarged spleen descending 18 cm. below the left costal margin. Examination of the blood disclosed the typical picture of chronic myelogenous leukemia. Following a course of roentgen therapy for three weeks the leukocyte count dropped from 148,000 to 10,700 cells per cubic millimeter of blood. At the end of this time a differential count revealed a few cells that were called pathologic monocytes in addition to monocytes which appeared normal morphologically. These so-called pathologic monocytes were observed on two examinations of the blood during the ensuing month. Two and a half months after the first admission, examination of the blood revealed the monocytes to number 45 per cent of the total leukocytes. Many young forms, including cells called ‘monoblasts,’ were present. Following the one observation in which monocytosis was noted, the patient was not seen again. She died two months later; necropsy was not obtained.”³

The Hall and Watkins case was a woman, 23 years of age, admitted to The Mayo Clinic on June 4, 1935. Symptoms were failing strength, progressive loss of weight, fever, and pain in the left upper quadrant of the abdomen; these were of four years' duration. One year previous to admission, however, fatigue, generalized weakness, loss of weight, anorexia, and episodes of chilliness with fever, resulted in physical incapacity to carry on as a housewife. Extraction of a tooth was followed by hemorrhage. Diagnosis was made by her physician of myelocytic leukemia. There followed pain in the left upper abdominal quadrant, with nausea and vomiting. Physical examination showed fever, rapid pulse, weakness, emaciation, pallor, and appearance of critical illness. Superficial lymph nodes were enlarged. The spleen was enlarged, reaching to the level of the iliac crest. The total white count was 600,000 cells. The typical picture of chronic myelocytic leukemia was seen in spreads, with myeloid immaturity to myeloblasts, the predominance of young forms being in the neutrophilic series. There was severe secondary anemia. After treatment, patient went home but after two months was returned to the Clinic. One month after her first visit the white count had dropped to 100,000; three weeks later it had risen to 400,000. X-ray therapy was advised. Examination at this time showed slight anemia and a white count of 60,000, with less myeloid immaturity in the blood spreads, the youngest forms found being neutrophilic promyelocytes; there were no myeloblasts or leukoblasts; 5 per cent of the leukocytes were monocytes. No monocytes were seen in the spreads at the time

of the first admission. Roentgen treatments were administered daily. After seven days, she was dismissed but returned after three months. The spleen had receded in size, and the leukocyte count was 13,400. There was no anemia. The blood films now showed the predominant cell to be the monocyte. At this time she had 51.5 per cent monocytes and 12.0 young monocytes. Immature granulocytes were infrequent. She was discharged but readmitted on Dec. 25, 1935, because of marked dyspnea, vomiting, and abdominal pain. Diagnosis at home had been pneumonia. Spleen had enlarged. At this time, she showed 58.0 monocytes, of which 23.5 per cent were young monocytes. She was taken home against the advice of attending physicians. At the time of dismissal, leukocytes were 36,000 cells per cubic millimeter, with blood picture the same as at the time of admission. She rallied but died, after two months, on March 7, 1936. Blood films showed at this time 59.0 per cent monocytes, of which 34.5 were young monocytes. No necropsy was obtained.

In this case there can be no doubt that there was a conversion in the blood picture from typical myelocytic leukemia to one that was clearly monocytic leukemia, and that after the monocytic leukemia had developed the monocytes could be traced back to stem cells. No cells typical of reticuloendothelial cells were seen in the circulating blood of this patient at any time. Therefore, Hall and Watkins believe that the monocyte was derived from a cell which possessed all the characteristics of the myeloblast. The number of stem cells seen in the blood after the picture of monocytic leukemia had developed was small. Hall and Watkins believe that a "monocytic phase" may develop at any time in the course of myelocytic leukemia or that the picture may be that of monocytic leukemia when the patient is first seen, later changing to one of chronic myelocytic leukemia which at a later date changes to one of monocytic leukemia as was demonstrated by the case above reported. Levine¹ reported a case which was studied for a long time because of severe anemia of indeterminate type. Ten days before death, a leukemic blood picture developed in which myeloid immaturity toward the stem cell, and mature and young monocytes were observed, with the findings at necropsy of subacute myelocytic leukemia. Levine expressed the opinion that this picture illustrated the development of a monocytic phase in the course of myelocytic leukemia after an initial aleukemic phase.

Hall and Watkins studied all of the cases of monocytic leukemia seen at the Mayo Clinic in a ten-year period and found that twenty-three cases were of the Naegeli type and six were of the Schilling type. They believe that the Naegeli type of monocytic leukemia should be considered a variant of myelocytic leukemia and the Schilling type a variant of leukemic reticuloendotheliosis.

The blood picture given below represents a typical case of monocytic leukemia of the Schilling type. The case record is from our service at the Christian Hospital, St. Louis, Mo., and was obtained through the courtesy of Dr. D. L. Twedell.

Patient was a 36-year-old white male, married, the father of one small child. Patient had been ill since March 21, 1942. Symptoms began with severe abdominal pain, general lymphadenopathy, especially of the groin and neck; fever, weakness, headaches, general malaise. Patient lost much weight. Condition became steadily worse, and patient entered a hospital. Two weeks later he transferred to the Christian Hospital. General condition: greatly emaciated, anemic looking, poor condition. Mentally very depressed, seeming to live in fear of dying. Liver and spleen enlarged, palpable, and tender. Heart sounds of fairly good quality. Bronchovesicular breathing showed no definite dullness. Moist râles

¹Levine, V.: *Folia haemat.* 52: 305, 1934.

over the bases. Kidneys not palpable. Patient had difficulty in urinating. Reflexes deep and superficial, weak.

On admission the pulse was 110; temperature, 101° F.; respiration, 28. Temperature gradually increased from 103 to 105°. The patient received 500 c.c. of citrated blood on the second, third, and sixth day of hospitalization. Patient expired one week after entrance.

Blood pictures follow:

There have been a number of erroneous conclusions about monocytic leukemia due to the fact that only single observations have been made on some cases. Thus, at various times, the features of agranulocytosis, aleukemic myeloid leukemia, aplastic anemia, leukemoid monocytosis, leukopenic infectious monocytosis, chronic splenic panhematopenia, and reticuloendotheliosis have been depicted. Monocytic leukemia may pursue a very erratic course. This was exemplified in the unusual case reported by Rappoport and Kugel¹ This case was exhaustively studied. There were four sternal punctures. There were several episodes of granulocytopenia. Serial blood counts were made and autopsy findings were very complete in this case, and the conclusion was drawn that this was unquestionably a case of true monocytic leukemia. The authors believe that the distinction between the Schilling and Naegeli types of monocytic leukemia is more apparent than real and does not deserve the rigid segregation frequently employed and heretofore alluded to in this chapter. A similar contention has been advanced by Campbell, Henderson, and Croom² and Custer.³ This case illustrated, as do most of the cases, that in the later stages of the disease, as the frank monocytic leukemia progresses, the myeloid reaction diminishes. This myeloid reaction is, for the most part, an expression of the bone marrow reactivity to the agranulocytosis and is not an expression of the monocytic leukemia.

There are certain essential facts which must be borne in mind relative to the diagnosis of this disease. One of these facts is the proper identification of the monocyte. It is usually larger than the granulocyte; its cytoplasm is opaque, mottled, gray-blue, and contains azurophilic granules. The cell margins are serrated and irregular. The nucleus is reniform or horseshoe-shaped and possesses a lacy, skeinlike, coarse chromatin weave. With supravital stain, numerous neutral red or salmon-pink colored bodies, vacuoles, are symmetrically arranged around a centrosphere located in the bay of the nucleus. This structure is the rosette which is considered so typical of the mature monocyte. Moreover, the monoblast measures from 15 to 20 μ in diameter and in fixed stained

³Quoted by Rappoport and Kugel from a personal communication.

films it possesses a basophilic cytoplasm containing no granules and, distinctively, no Auer bodies. The nucleus is round, large, and centrally situated; its chromatin is fine, stippled, and sievelike, and usually possesses two nucleoli.

Rappoport and Kugel emphasize that this diagnosis requires prolonged and intensive clinical and laboratory observations. The differential diagnosis depends solely upon the results of bone marrow examinations. The presence of "reactive" or "irritative" or the leukemoid phenomena or intoxications must be considered and evaluated in the differential diagnosis.

Lymphocytic Leukemia Following Benzol Poisoning.—Falconer¹ reported a case of chronic benzol poisoning, gradually developing the picture of a typical leukemia as follows:

This man, aged 58 years, was employed in a can factory. The can ends, rimmed with a solution of rubber in benzol, were delivered to him by a conveyor, the benzol evaporating from the rubber mixture en route. Falconer had seen four cases of typical benzol poisoning from the same plant during the previous year. This patient's blood studies showed 50% hemoglobin, 1,530,000 red blood cells, 8,100 white blood cells, 62% neutrophils, 32% lymphocytes and 6% monocytes. Blood platelets numbered 68,000; red cells showed anisocytosis and some polychromasia. The symptoms were diagnosed as chronic benzol poisoning. Later on, hemorrhages from the nose began, together with decrease in red and white counts. After a blood transfusion, the nasal bleeding ceased. About a month later he returned for treatment, and two months later the bleeding from the nose reappeared. The blood picture showed decrease in the number of red cells and amount of hemoglobin, but white cell volume rose. About four months later, he showed a picture of beginning lymphocytic leukemia, the counts running up to 50,000. This state persisted for about a year when death occurred, with a clinical diagnosis of lymphocytic leukemia.

There were three important questions suggested by a study of the clinical data and autopsy material on this patient. The autopsy material, by the way, showed general lymphadenopathy, increase in size of spleen, leukemic infiltration of liver and kidneys, secondary anemia, bronchopneumonia, and purulent bronchitis. The lymph nodes showed a striking overgrowth of tissue by a type of cell which was larger than the usual lymphocyte and which contained a thin rim of cytoplasm. The bone marrow showed the same type of cell as the lymph node.

The questions are:

1. What effect does benzol have on lymphatic tissue?
2. Is it not possible for benzol, like other well-known hemopoietic irritants, to upset the hemopoietic balance between cell growth and destruction, giving rise to lymphoid hyperplasia?
3. Does this lymphoid hyperplasia always stop just short of leukemia, or can it, under prolonged irritation or in susceptible individuals, progress to lymphocytic leukemia?

Lignac² injected mice with from 25 to 30 injections of benzol (0.1 c.c. of 0.3 c.c. benzol in 10 c.c. olive oil) and concluded that the symptoms of hyperplasia developed and that the spleen, which was first hypertrophied, decreased in size. The animals showed hyperplasia but no lymphocytic leukemia. He did not succeed in producing lymphocytic leukemia. The hyperplasia he con-

¹Falconer, E. H.: *Am. J. M. Sc.* 186: 353, 1933.

²Lignac, G. O. E.: *Krankheitsforschung* 6: 97, 1928.

sidered as a tumorous growth similar to leukemia. It is a real tumor of precursors of white blood cells. He stated that the immaturity of undifferentiated cells suggests acute leukemia, and the development of tumor may, or may not, be accompanied by a leukemic blood picture.

Thermal and Chemical Influences on Hematopoiesis.—

Murphy and Sturm² reported experimental work with hemopoietic irritants, accomplished by subjecting mice, rats, and guinea pigs to dry heat at temperatures of from 55° to 65° C. with short exposures of about 5 minutes; white counts were made at intervals over a 3-week period. The blood picture showed an immediate drop in both neutrophils and lymphocytes, which averaged about 3,000 cells per cu. mm. Seven days after the heating, there was an increase of from 5,000 to 10,000 cells per cu. mm., the increase being almost entirely in the lymphocytes. Fourteen days after heating, the lymphocytes had increased to from 12,000 to 14,000 per cu. mm. above the original counts; the neutrophils remained low and did not increase until about three weeks after heating. From 6 to 10 days after heating, several lymphocytes were noted apparently in process of amitotic division. These cells in the process of division looked very much like the cells reported by Falconer in his case of leukemia following benzol poisoning.

Nakahara,³ in trying to determine the source of lymphocytosis induced by heat, found the first change in the spleen and the lymph glands with widespread degeneration of the lymphoid elements. This was followed in 48 hours by activity of the "germinal centers" with an overproduction of lymphocytes, the spleen and lymph glands becoming larger than normal. There was a marked increase of mitotic figures in the lymphocytes of the germinal centers following the general necrosis.

Benzol presumably may act on lymphatic tissue in a manner similar to dry heat, causing destruction first then a compensatory hyperplasia, exceeding the normal limits. It is questionable whether this might not later result in leukemia.

The influence of chemicals on lymphatic tissue has been studied. Isaacs⁴ found that arsenic acts as a depressor of the bone marrow with decreased production of young red blood cells. If arsenic is stopped, the bone marrow responds once more with an increase in the rate of maturation of the erythroblastic tissue and an increased production of young red blood cells. Balbridge, Rohner, and Hausmann⁵ found six cases of infectious mononucleosis which developed under antisyphilitic treatment. White⁶ reported a case of infectious mononucleosis which also developed under antisyphilitic treatment. Falconer in 1925 (unreported) observed a case with infectious mononucleosis with a severe Vincent's infection of the buccal cavity after neoarsphenamine administration in syphilis.

Farley¹ and others believe that the benzol ring in arsphenamine and its derivatives may be responsible for hemopoietic tissue damage. Others, such as Sternberg,² suggest that acute leukemia is an infection. Cabot³ reported leukemoid blood pictures following lymphangitis, furunculosis, acute streptococcus tonsillitis, and cervical adenitis. Herz⁴ mentioned cases of infection with a blood picture simulating lymphocytic leukemia. Marchand⁵ reported a case of severe sepsis with bone marrow exhaustion and a picture of lymphoid hyperplasia.

This report does not prove that benzol may cause lymphocytic leukemia. It does stimulate regeneration of the erythropoietic and leukopoietic tissue, chiefly in the bone marrow. In an individual with a labile lymphatic apparatus as Farley's case, the lymphatic response may be unusual and carry on to a leukemic state. The individual was a short, obese patient with hypertrophied tonsillar tissue, who might be termed a "lymphatic" type.

The effect of radium and x-rays on hemopoietic tissue has not yet been worked out. Cases of leukemia and of aplastic anemia in workers exposed to x-ray and radium have been reported. Emile-Weil⁶ reported two cases in engineers working in the same laboratory with radioactive material. One died with pernicious anemia and the other with myelocytic leukemia. Farley⁷ states, "In view of the undoubted production of aplastic anemia by the action of rays on the bone-marrow, it is not surprising that the production of a myelogenous type of leukemia by rays should be reported, but the production of lymphatic leukemia by such means should not be credited without very close scrutiny."

Experimental work carried on at the Rockefeller Institute⁸ shows that with a certain dose of the roentgen ray, a lymphocytosis similar to that produced by heat can be brought about, that is, first a lymphocyte fall, followed by a marked rise.

Studies^{9, 10} on people exposed to atomic bomb radiation in Hiroshima and Nagasaki revealed 75 cases of leukemia, indicating a great increase in incidence of this disease in the survivors of this exposure. The predominant form was chronic myelocytic leukemia, but it has been pointed out that lymphocytic leukemia is rare in Japan. The leukemogenic effect of ionizing radiation was distributed equally in all age groups and in both sexes. In some of the cases there was a prolonged latent period of several years before development of the disease. In these preclinical stages, disturbances of the red cells and platelets as well as of the leukocytes were noted. An increase in basophiles, many of which were abnormal, was one of the outstanding features. These authors

hypothesize that disturbances in cell enzyme systems with a resultant loss or alteration of cell growth-promoting or regulating factors account for the leukemic changes.

Basophilic (?) Leukemia

There is some dispute as to whether or not there is actually an entity which may properly be called basophilic leukemia. Many contend that these are cases of chronic myelocytic leukemia with large numbers of basophiles. Groat and others¹¹ reported a case of acute basophilic leukemia which seems to bear out their belief that this entity may actually occur. They cite the report of Joachim,¹² who in 1906 reported two cases of chronic leukemia in both of which the percentage of mast cells or basophilic cells was above 50. The blood picture in Joachim's case was of an ordinary chronic myelocytic leukemia except for the large number of mast cells, as high as 83%. Joachim's opinion was that the general symptoms were similar to other chronic myelocytic leukemias except for the degree of basophile increase. He reported it as a case of atypical leukemia, concluding that chronic basophilic leukemia is a variety of the common myelocytic variety. Sabrazès¹³ in reporting a case of chronic myelocytic leukemia with many mast cells stated that the so-called hemohistioblast of Ferrata and many types of basophiles were frequently found increased in chronic myelocytic leukemia. Elliott and Young¹⁴ reported a case of chronic mast-cell leukemia because of predominance of leukocytes with coarse basophilic granulation.

The case reported by Groat and others was a young man, 27 years old, with a blood count of 186,000 white blood cells on first observation, but no basophilic element was originally present. Having been treated with roentgen ray applied to the splenic area, he returned some months later with a total count of 10,200 white cells and 2% basophiles. About two months later, his blood showed 12% basophiles. He died about two months after the above observation after repeated x-ray treatments. Post-mortem bone marrow examinations showed eosinophilic myelocytes in large numbers and many myelocytes, which were probably divided between the basophilic and neutrophilic types. Megakaryocytes were present in small numbers. Groat concluded that they would like to call their case acute myeloblastic leukemia with extreme basophilia but believed that the term "basophilic leukemia" should be retained until more complete evidence and confirmation has been presented. He stated that one may consider these numerous basophiles as the progeny of the leukemia myeloblasts potentially basophilic.

Casey, Nettles, and Hidden¹⁵ discussed what has already been stated in this book; namely, whether there is a true basophilic leukemia distinguishable from the neutrophilic type. Doan and Reinhart¹⁶ reported three cases which they believed to be true basophilic leukemia. They seemed to believe that these were the first instances of this sort to be reported.

The case reported by Casey and associates, which records the sixth case in the literature with clinical observations for at least one month before death, emphasized that there is no evidence at present that basophilic leukemia ever

occurs except as a terminal phase of neutrophilic leukemia. They made a very proper recommendation for future observers; namely, that only those cases should be reported as basophilic leukemia in which (1) blood studies using supravital and peroxidase stains, together with routine blood examinations, have been made; (2) hematologic observations on the patient have been available for more than 3 months prior to death; and (3) post-mortem examination with supravital studies of spreads from bone marrow, blood, spleen, lymph nodes, and alcohol fixation of the tissues for the preservation of the water-soluble basophilic granules have been made.

In a discussion of this paper before the Southern Medical Association, Robert A. Moore came to the same conclusion; namely, that this is a terminal discharge of cells. The disease is basically myelocytic leukemia. He believes also that extreme eosinophilia in myelocytic leukemia does not change the basic diagnosis.

Plasma Cell Leukemia.—

In the literature there have been 36 cases of plasma cell leukemia reported. Foa¹ reported the first case. He called it pseudoleukemia plasmacellularis. He found plasma cells in the blood and diffuse infiltration of the bone marrow, liver, spleen, and in some lymph nodes. Moss and Ackerman² reported a case in September, 1946. This man showed symptoms of swelling of the lower jaw, bleeding gums, enlargement of the spleen and liver. The blood picture showed 13,700 leukocytes, with a differential count of 4 per cent myelocytes, 14 juveniles, 15 stabs, 24 segmented neutrophils, 23 lymphocytes, 6 monocytes, 2 eosinophiles, and 1 per cent basophiles, with 11 per cent plasmacytes, 4 per cent pronormoblasts, and 24 per cent normoblasts. The sternal bone marrow showed the marrow completely replaced by plasma cells. Diagnosis of plasma cell leukemia was made. Plasma cells reached a maximum value of 22 per cent. There was a hyperglobulinemia throughout the disease. Autopsy one and one-half months after admission to the hospital showed splenic enlargement, liver enlargement, and microscopically, plasma cells present in every region of the liver. Spleen sinuses were plugged with plasma cells. Lymph nodes showed invasion of plasma cells, likewise the pancreas. Both marrow showed a complete replacement of normal elements by a diffuse infiltration of plasma cells.

In reference to clinical findings in this disease, it is usually found between the ages of 45 and 60. In contrast to multiple myeloma* in which 70 per cent are males, neither sex shows a predisposition for plasma cell leukemia. The early symptoms of plasma cell leukemia in the majority of cases are those of multiple myeloma. Pain in the arm, back, legs, or substernal region may be present, with a history of lassitude, weakness, and weight loss. There is a tendency to hemorrhage. Bleeding is nearly always from the gums and nose. Bone destructive nature of plasma cell leukemia is exemplified by frequent pathologic fractures. In the bone marrow there is diffuse infiltration with

*Refer to page 927.

¹Foa, P.: Mem. d. r. Accad. sc. Torino 52: 259, 1902. Abst. Folia haemat. 1: 166, 1904.

²Moss, W. T., and Ackerman, L. V.: Blood 1: 5, 396-406, Sept., 1946.

plasma cells. These cells do not differ from those in the blood, except that in the blood the plasma cells tend to be smaller. Liver is invaded by plasma cells, likewise the spleen and lymph nodes.

Differential Diagnosis.—Askanazy³ formulated the following as requirements for a diagnosis of plasma cell leukemia:

1. Plasma cells must be present in the peripheral blood.
2. Leukocytosis.
3. Diffusely involved bone marrow.

A bone marrow biopsy showing diffuse plasma cell infiltration, together with finding the typical cell in the circulating blood, is necessary and usually sufficient. Plasma cells may increase to 30 per cent in measles, in rubella, rubeola, scarlatina, in chronic lymphocytic leukemia, and occasionally in myelocytic leukemia, metastatic carcinoma, and Hodgkin's disease.

On the other hand, bone marrow infiltration by plasma cells unaccompanied by more than occasional plasma cells in the circulating blood may be found in hepatic cirrhosis, agranulocytosis, and miliary tuberculosis.

Laboratory Findings.—In plasma cell leukemia the leukocyte count is usually 10,000 to 40,000. The percentage of plasma cells found in the peripheral blood varies from 87 per cent to 1 per cent. Erythrocyte count is low. Anemia follows the same pattern as in other leukemias. There is a low blood platelet count which is reflected in the high percentage of hemorrhagic tendencies found. Just as in multiple myeloma, hyperglobulinemia is sometimes present in plasma cell leukemia.

Bence-Jones Bodies.—The test for Bence-Jones bodies in the urine was performed in 20 of the 37 cases of plasma cell leukemia. Six of these were positive and the rest negative. A positive test is good evidence of multiple myeloma, for it is infrequent that Bence-Jones bodies are found in diseases other than multiple myeloma.

Although a series of transitions from typical multiple myeloma² to typical plasma cell leukemia has been arranged by Piney and Riach,⁴ and has been discussed by numerous workers,^{5, 6, 7, 8} and the entire series of cases reviewed might be classified more or less in order from those typical of multiple myeloma to those which resemble typical leukemia, it is doubtful if such a list would contribute to knowledge of the disease.

If, as Patek⁷ implied, the more nearly plasma cell leukemia resembles a typical leukemia, the more malignant the disease, the readiness with which plasma cells tend to enter the blood stream should be a measure of malignancy. This seems logical, but it has not been proved. In multiple myeloma the average duration of life after recognition of symptoms is 2 years,⁹ while in plasma cell leukemia it is 8 months. Cases of plasma cell leukemia with an initial plasma cell count in the peripheral blood of over 50 per cent (4 cases) had an

⁹Geschickter, C. F., and Copeland, M. M.: *Arch. Surg.* 16: 807, 1928.

average duration of life of 5 months, while those with an initial plasma cell count under 20 per cent (15 cases) had 8 months' duration. Patek concluded that with such a small number of cases, not much significance can be attached to these figures, but it does suggest that the readiness with which plasma cells enter the peripheral circulation is a measure of the malignancy.

Since multiple myeloma is a leukocytic tumor, the occurrence of leukemia in certain cases brings up again the close relationship between the leukocytic neoplasms and leukemia, the latter probably being a generalized variant of the former condition.

Aleukemia or Leukemia Without Leukocytosis

This class is so-called from its histologic and pathologic-anatomic symptoms. There are anemia, enlarged glands, and splenic tumor. These cases may show a leukemic blood picture with almost a *normal total count*. Aleukemic conditions may be temporary or may change into manifest leukemia. Pinkus believes that the lymphocytic aleukemia is the most common variety. The blood picture rarely approaches normal. There is a relative and sometimes an absolute lymphocytosis with normal or high normal counts. According to Schilling, there is a high-grade regenerative shift. There are 60 per cent lymphocytes, with occasional lymphoblasts. These cases are characterized by lymphoblasts, atypical lymphocytes, Rieder forms with lobulated nuclei, in conjunction with signs of a severe anemia.

Many authoritative sources have reported cases of leukemia without leukocytosis and without enlargement of the spleen. Hirschfeld,⁴ for instance, reported four cases of leukemia without splenomegaly. Ordway and Gorham⁵ reported one case, and Kracke and Garver⁶ also described one case. Weber⁷ reported one case of aleukemic myelosis without splenic enlargement in which the condition clinically simulated aplastic anemia. He believes that many cases, in which the clinical diagnosis was aplastic anemia, were undoubtedly examples of aleukemic myelosis. In other words, we can now speak of the condition called aleukemic myelosis, which is leukemia without leukocytosis and without enlargement of the spleen. Mettier and Purviance⁸ reported five cases of leukemia in patients who had no leukocytosis and no splenic enlargements. The clinical findings were those of severe anemia, thrombopenia, and leukopenia with the presence of immature forms of leukocytes in the stained films of blood.

The first case showed 7,600 leukocytes per cubic millimeter with a differential count of 39% segments, 2% nonsegments, 45% lymphocytes, 3% monocytes, 4% myelocytes, 5% myeloblasts, and unclassified immature forms, 2%. One nucleated red blood cell was seen per hundred white blood cells. There was a diminution in the number of blood platelets.

The patient presented the clinical symptoms of a severe blood dyscrasia and died following hemorrhage from the bladder and gastrointestinal tract. The clinical diagnosis was aleukemic myelosis with slight leukemic metaplasia of the cervical lymph nodes. Section

of this cervical lymph node showed that the architecture of the lymph node had been largely replaced by tumor cells of various sizes, mostly of the myeloid type. There were myelocytic cells of the neutrophilic and eosinophilic types present.

A second case was a 38-year-old white man who showed 2,300 leukocytes or a very definite leukopenia, with a differential count of 7% polymorphonuclears, 22% nonsegmented neutrophils, 42% lymphocytes, 26% monocytes, 1% myelocytes, and 2% unclassified cells. Two nucleated red blood cells were seen per hundred leukocytes in the stained film. Blood platelets were found greatly reduced. This patient showed anemia and leukopenia with no apparent hematopoietic reaction to liver extract given either parenterally or by mouth. After a number of weeks the patient returned to the hospital, from which he had been discharged, with the same picture with 20% myelocytes, and 16% myeloblasts, and 40,000 platelets per cubic millimeter. Clinical diagnosis was aleukemic myelosis with anemia and thrombopenia.

There were several other cases reported of similar type.

It is interesting to note that the biopsy of the bone marrow from the sternum afforded a valuable aid in establishing the diagnosis. Specimens of the marrow showed a predominance of undifferentiated types of cells, many of which contain mitotic figures, packed solidly together, to the exclusion of fat cells. This picture of the bone marrow indicated a hyperplasia which was undoubtedly leukemic.

Diseases Simulating Leukemia

Lymphosarcoma.—This term has been used loosely to cover all neoplastic states of lymph nodes that are not clearly Hodgkin's disease or leukemia. Strictly speaking, lymphosarcoma is a disease in which there is a neoplastic transformation of the lymphocytic strain of cells. Hematologically lymphosarcoma may show no detectable changes in the peripheral blood except perhaps a secondary anemia or an occasional low-grade lymphocytosis, or both. The neoplastic cells may break over into the blood stream in greater or lesser number, producing a type of leukemia first described by Sternberg⁹ as leukosarcoma. Wiseman records the results of a series of blood examinations made in a case of lymphosarcoma in which the tumor type of cell (in contrast to normal lymphocytes) was found in the blood stream only intermittently. This case, histologically, answered the description of the tissue described by Brill, Baehr, and Rosenthal¹⁰ under the term "follicular lymphoblastoma" and is the most chronic type of leukosarcoma encountered.

Chloroleukemias.—This is a disease described by Naegeli. It displays an acute leukemic blood picture. The symptoms are cachexia, severe anemia, and subperiosteal circumscribed proliferations, manifested principally on the skull.

Leukosarcomatosis.—This was classified by Sternberg as a separate group. These cases show the picture of acute leukemia of the myelocytic and lymphocytic varieties with highly infiltrated tumor growths.

Pseudoleukemia.—This term is a misnomer and should be replaced by the term "apparent leukemia." These cases fall into the following: (1) malignant granuloma or lymphogranulomatosis, also called Hodgkin's disease; (2) generalized tuberculous granuloma of the lymph glands; (3) generalized syph-

⁹Sternberg, C.: Ueber Leukosarkomatose, *Wien. klin. Wchnschr.* 21: 475, 1908.

¹⁰Brill, N. E., Baehr, George, and Rosenthal, Nathan: *J. A. M. A.* 84: 668, 1925.

ilitic granuloma; (4) myelogenous metaplasia through osteofibrosis, the so-called "marble" disease, tumors of the bone marrow with myelogenous enlargement of liver, spleen, and glands.

Lymphogranulomatosis Maligna—Hodgkin's Disease

This disease was described by Hodgkin in 1832 in a publication entitled, "On Some Morbid Appearances of the Absorbent Glands and Spleen."¹ Many observations have been made since that time. Considerable experimental work has been done, but the etiological agent has not yet been discovered. This disease was once called "pseudoleukemia." Bonfils in 1856 spoke of it as a cachexia without leukemic changes. Virchow in 1865 classified it with the lymphosarcomata. Cohnheim, unfortunately, introduced the term "pseudoleukemia," but this has been proved to be manifestly an incorrect classification. Billroth in 1869 called it "malignant lymphoma"; Langhans in 1872, "malignant lymphosarcoma"; Schulz in 1874, "reticulated desmoid carcinoma"; Orth in 1887, "malignant aleukemic lymphadenoma"; and Langebeck termed it "gland sarcoma." Many regard it as an infectious granuloma due to a specific microorganism, although this microorganism has not yet been identified.

So far as predisposing causes are concerned, it seems to occur in males three times as frequently as in females. Age incidence is a well-defined factor. The preponderance of cases occurs in young adults and in middle-aged individuals, one-third appearing before the twentieth year and one-half between the twentieth and fortieth years.

Geographically, it occurs in all parts of the world, sparing no race. There are no data on hand to show any etiological basis from the standpoint of family predisposition. It is striking that the greater number of cases appear in individuals of robust constitution, previously in apparently good health. The disease is likely to occur among the rich as well as among the poor. There is no information at hand to show that any previous disease plays a role in the excitation of this disease.

Some believe in the infectious nature of this disease because of the histopathologic evidences found in the affected tissues. The positive character of this evidence is the resemblance exhibited by the changes produced in the glands to those caused by other infectious diseases, particularly syphilis and tuberculosis. There is great dissimilarity between this disease and the clinically similar leukemic and lymphosarcomatous lymph node enlargements.

Many organisms have been described as the etiological agents of this disease but none have stood the test of time. Some have claimed that the tubercle bacillus causes Hodgkin's disease; others that it is due to the pseudodiphtheria bacillus; and even the "bacterium hodgkini" has been ardently brought forward as the causative bacteriologic agent of this disturbance.

Wise and Poston* allude to the coexistence of brucellosis and Hodgkin's disease, which is in line with those who believe in the infectious origin of this disease. *Brucella* were found in fourteen cases of Hodgkin's disease by isolation of *Br. melitensis* by blood or lymph gland culture.

*Wise and Poston: J. A. M. A. 115: 1976, 1940.

¹Hodgkin, T.: Med.-Chir. Tr. 17: 68, 1832.

Summarizing, the condition is truly a granuloma of unknown origin. It may be bacterial or virus in origin. According to the view of Brill and Symmers, it holds an intermediate position between an infectious granuloma and a true tumor. Ewing's work points to the transition of Hodgkin's granuloma into a sarcoma, although Krumbhaar in a large series of cases with autopsy findings does not believe that Hodgkin's disease can develop into a Hodgkin's sarcoma.

Symptoms.—Trousseau has divided the clinical course of Hodgkin's disease into two phases: (1) that of the local enlargement of the lymph nodes, known as the "latent period"; and (2) that of the "generalization" of the process with the involvement of the lymph glands generally, of the spleen in most cases, and of other organs, and of progressive cachexia. The latent period is characterized by the patient's noticing something wrong with his appearance, such as a growth on one side of the neck, which is not painful, is not tender, and in no way seems to affect the general health. Sometimes in the case of nonobservant individuals, the patient presents himself only after a rather enormous enlargement at the side of the neck has developed. The duration of the so-called "latent" period is variable, depending upon the virulence of the infection and upon the resistance of the individual. It may vary from several weeks to four years or more.

The second period of Trousseau witnesses the "generalization" of the process, the involvement of other lymphatic structures, and of other organs, febrile phenomena, and the appearance of anemia and cachexia. The lymphatic gland enlargement, which began in the neck, extends to the opposite side, is followed by enlargement of the axillary, inguinal, and other superficial groups; this in turn is followed by involvement of the deeper glands. Spleen and liver enlargement with signs of pressure phenomena exerted upon the lungs, pleurae, hilus of the liver, nerve trunks, and veins occur. Fever is present followed by changes in the blood, but these blood changes are not characteristic.

Serious involvement of the central nervous system occurs in this disease. The changes in the nervous system are damage to the spinal cord, due to direct pressure caused by extradural deposits of the abnormal granulomatous tissue by disease on one or more vertebral bodies with consequent angulation, and also a degeneration resulting from interference with the blood supply of the cord. Actual inflammatory and degenerative changes in the cord substance have been observed by Forrest,¹ Shapiro,² Weber,³ and Weil.⁴ A later observation on the invasion of the spinal canal by lymphogranulomatosis maligna is that by Cooper.⁵ He reported a case of lymphogranulomatosis maligna with invasion of the spinal canal and concluded that nerve roots afford a route by which lymphogranulomatous tissue may reach the subdural space, probably through the lymphatic spaces of the roots rather than

⁵Cooper, M. J.: *J. A. M. A.* 102: 917, 1934.

by the substance of the nerve fibers. The spinal dura mater is relatively more resistant to penetration than are the septums of the nerve roots. Paraplegic symptoms may result not only from direct cord compression but from obstruction to the circulation of the cord as a result of compression or invasion of the vessels accompanying the nerve roots.

In addition to the lymphatic gland enlargement, the spleen is usually involved with moderate enlargement, although enormous tumors are occasionally observed. Sometimes, enlargement of the tonsils is noted. Most of the circulatory symptoms are due to compression. The liver often participates in the process. Clinical symptoms are the enlargement of the organs. Jaundice is sometimes seen, due to compression of the common duct by the lymphomatous masses. The cause of diarrhea, which is commonly found in this disease, is not known, but it is probably a toxic manifestation. Nodules are sometimes seen in the osseous system. There are two types of symptoms in the cutaneous manifestations, the one due to the specific process, consisting of the deep-seated, destructive changes made up of the characteristic granulation tissue of the disease, and the other in all probability also specific and consisting of the superficial, ephemeral lesions which are probably of toxic origin. Pruritus occurs in about 10 per cent of the cases; in association with the diarrhea and the lymphatic gland enlargement, it is of considerable diagnostic importance. Pigmentation is another cutaneous symptom sometimes occurring as the result of the itching lesions, but frequently not associated with pruritus and of unknown cause.

The Blood Picture.—The hematologic picture of this disease has been a subject that has been much discussed. *Certain it is at this time that there is no characteristic picture in the blood by which one can identify the disease as Hodgkin's disease.* There are changes, it is true, but they are not characteristic. The red cells are reduced in number and there is usually a diminution in the percentage of hemoglobin. The red cell count may vary from 2 to 4 million, but sometimes drops to the million mark. The red cells are pale and there are often many microcytes. Occasionally, nucleated red cells are seen, together with poikilocytosis, polychromasia, and basophilic punctation. The number of white cells varies. Occasionally Hodgkin's disease displays an unusual increase in the number of white cells, but this increase is not a characteristic phenomenon. There may be a leukocytosis as well as a leukopenia. McAlpin¹ found the cell count ranged in eighteen cases between 2,000 and 13,000.

Ziegler² in seventy cases found the following: in 22, counts of from 5,500 to 10,000; in 20, from 10,000 to 20,000; in 8, from 20,000 to 30,000; in 2, more than 30,000; and in 18, a leukopenia of from 2,000 to 5,500. In a general way, there is usually in the early stages of the disease a slightly increased total count, or perhaps a normal count. The differential count has been much discussed but as yet no one has had the temerity even to suggest that there is any possibility of making a diagnosis of Hodgkin's disease from the differential count. Early in the disease there may be a lymphocytosis, but this is not positive. A leukopenia with a relative lymphocytosis has been described in

¹McAlpin: Arch. Int. Med. 33: 954, 1933.

²Ziegler: Hodgkin's Disease, Jena, 1911.

the beginning of the disease. Much emphasis has been laid upon the *eosinophilia* in Hodgkin's disease, but this has been denied by others. Our own experience has shown only a slight eosinophilia, but that the eosinophilia in the blood runs parallel with a tissue eosinophilia admits no denial. This may be due to the fact that the chemotactic influences exerted by the specific granulation tissue upon the bone marrow bring in response not only the number demanded by the tissues but, as is usual, an excess, which enters the circulating blood and accounts for the eosinophilia. *The eosinophilia, if present, is of diagnostic importance, but if absent, is not sufficient to exclude this disease.*

A very interesting observation has been made by the author in three cases of Hodgkin's disease. This observation is offered here not as a diagnostic measure but as a pure matter of record. In three different independent cases observed in three years, we have noted a rather peculiar condition of the red cells in Hodgkin's disease. Blood diluted with Hayem's solution for the red cell count has shown distinct clumping of the red cells, making it rather difficult in these cases to perform an accurate red count. The blood in these cases when diluted with 2.5 per cent sodium citrate solution did not display any clumping. The fact that this was observed in three independent cases of clinical and pathologic Hodgkin's disease certainly deserves mention. So far as we know, it has not hitherto been mentioned in the literature.

The actual diagnosis of Hodgkin's disease can be made only by excision of the lymphatic gland and histopathologic study. The characteristic picture of the lymphatic gland in this disease is as follows: first, a partial replacement of the normal lymphatic tissue by a new growth of connective tissue; second, the finding of rather typical cells (see Fig. 208) which have been well described by Reed in her studies on "The Pathological Changes in Hodgkin's Disease."*

In addition to the new growth of connective tissue, there are endothelial and reticulum cells, the formation of characteristic giant cells and often a large number of eosinophiles.

The Diagnosis of Hodgkin's Disease by Aspiration Biopsy

Biopsy by means of aspiration through a needle has been repeatedly described.¹⁻⁵ Loseke and Craver⁶ described their five years' experience in establishing the diagnosis of Hodgkin's disease and related diseases by means of aspiration biopsy. Their method is to aspirate tissue into the bore of a hollow needle.

Method.—

Accurately localize the site within the tumor into which the point of the aspirating needle is to be inserted.

Prepare the overlying skin by shaving, if necessary, and with iodine and alcohol.

With 1% Novocain anesthetize a wheal at the site in the overlying skin selected as the appropriate place for introduction of the needle.

⁴Idem: Surg., Gynec. & Obst. 59: 578, 1934.

⁵Pavlovsky, Alfredo: Thesis, Buenos Aires: A. Lopez, 1934.

⁶Loseke, L., and Craver, L. F.: Blood 1: 1, 76, Jan., 1946.

Make a tiny incision clear through the skin with a No. 11 Bard-Parker bistoury, so that elastic fibers of the skin will exert no drag on the needle.

Carefully introduce an 18-gauge needle (accurately fitted with a stylet, and having a rather short bevel) through the incision in the anesthetized skin until the point of the needle reaches the desired site within the tumor.

Remove the stylet and attach a 20 c.c. Record syringe to the needle. Draw the piston back so as to create a strong negative pressure within the needle-syringe system. While this negative pressure is maintained, slightly advance and withdraw the needle a few times, sometimes with rotation. If negative pressure is partially lost by leakage, detach the syringe and expel the air from it; then reattach it and again produce negative pressure.

When soft tumors are being aspirated, from 0.5 to 3.0 c.c. of bloody material may be sucked into the syringe. Firm or hard tumors may yield only a tiny bit of tissue, found within the bore of the needle. Occasionally nothing significant will be obtained, and the procedure may have to be repeated, if possible.

Allow the pressure within the syringe to become nearly normal, so that when the needle is withdrawn there will be no spattering of blood and tissue inside the syringe; then withdraw the needle.

Fig. 205.—Case 1. Section of clot obtained from infiltrated portion of left upper lobe of lung by aspiration biopsy. Diagnosis of Hodgkin's disease was made by means of this section confirmed clinically by subsequent course. (Loseke, Lucile, and Craver, Lloyd F.: *Blood*, J. Hematol. 1: 1, 1946. Courtesy Grune & Stratton, Inc., New York.)

Allow any material collected within the syringe to clot, if it will. Remove the clot, place on a small square of blotting paper, and then drop into a small "biopsy" bottle containing 10% Formalin. Prepare paraffin blocks, as for any tissue biopsy, and section.

Push out material in the needle by means of the stilet and blow onto slides. Other fragments may be found inside the syringe walls or on the face of the piston. Crush the material firmly and spread between slides; quickly stain with hematoxylin and eosin. This procedure is known as the "immediate spread."

The procedure used when a tumor within the chest is aspirated does not differ essentially from that described above.

Loseke and Craver⁶ found that in a study of 242 cases of histologically proved Hodgkin's disease, the diagnosis was established by open biopsy in 228, while in 14 cases aspiration biopsy yielded a reliable diagnosis.

⁶Loseke, L., and Craver, L. F.: *Blood* 1: 1, 76, Jan., 1946.

It is interesting to note that in cases of Hodgkin's disease without enlarged peripheral lymph nodes, yet presenting nodes or masses accessible to needle puncture, the method of aspiration biopsy has often proved successful in establishing the diagnosis. Success depends in large measure on examination, by an experienced pathologist, of a sectioned clot from the aspirated tissue.

Diagnosis of Case 1⁶ was made from Fig. 205. This was a case of infiltration in the anterior part of the left upper lobe of the lung. It might have been tuberculosis, bronchogenic carcinoma, or Hodgkin's disease. There were no enlarged peripheral nodes. Aspiration biopsy of the lung gave an immediate spread which yielded insufficient tissue, but the clot showed Hodgkin's disease.

The case illustrated in Fig. 206 was the fourth clinical case reported by Loseke and Craver.⁶

Fig. 206.—Case 4. A. Aspiration biopsy from spleen before any nodes were available, showing Hodgkin's disease.

B. Section of surgical biopsy from axillary lymph node two months later, confirming diagnosis obtained by spleen biopsy. (Loseke, Lucile, and Craver, Lloyd F.: *Blood*, J. Hematol. 1: 1, 1946. (Courtesy Grune & Stratton, Inc., New York.)

The onset of illness had occurred two years before, with general severe itching. There had been a weight loss of from 35 to 40 pounds over two years, and night sweats and intermittent fever for one year. Dyspnea and wheezing were present. Widespread excoriation of the skin from scratching, emaciation, and an appearance of chronic illness were found. Spleen was enlarged to the level of the iliac crest. Liver was enlarged by two fingerbreadths below the right costal border. There was roentgenographic evidence of some widening of the superior mediastinum, and of hilar infiltration. Moderate anemia was present. No peripheral nodes were suitable for biopsy. Aspiration biopsy of the spleen was made and the spread gave evidence consistent with the criteria for Hodgkin's disease. The clot showed Hodgkin's disease. Later, an enlarged

⁶Loseke, L., and Craver, L. F.: *Blood* 1: 1, 76, Jan., 1946.

node was found in the left axilla. Biopsy of this node confirmed the diagnosis of Hodgkin's disease. Fig. 206 is a section of surgical biopsy from axillary lymph node confirming diagnosis obtained by spleen biopsy.

The blood picture of a case of Hodgkin's disease observed in 1928 at the Christian Hospital, in St. Louis, was as follows:

Woman, aged 29, showed clinical enlargement of lymphatic glands in the neck and groin.

Red cells, 4,370,000; Leukocytes, 5,600; Hemoglobin, 77%; Color Index, 0.8.

Hemogram as follows:

Bas.	Eos.	Myel.	Juv.	Stabs		Segs.	Lymphs.	Monos.
1	1	0	0	4		69	22	3

A second hemogram three days later showed:

Bas.	Eos.	Myel.	Juv.	Stabs		Segs.	Lymphs.	Monos.
3	1	0	0	5		76	13	2

The thick drop showed 2+ polychromasia.

The following changes in the erythrocytes were noted: 1 megaloblast and 1 reticulocyte to the field. The Wassermann, Kolmer, Kahn, and Hecht-Gradwohl tests were negative.

Microscopic examination of tissue from gland of the neck showed a lymphatic gland structure with many large cells, evidently Reed cells, many eosinophiles with areas of focal necrosis in the gland. There was marked fibrous connective tissue reaction. Note on this record reads: "We are inclined to believe that this is a case of Hodgkin's disease rather than a lymphosarcoma."

Fig. 207.

Fig. 208.

Fig. 207.—Section of lymph node, Hodgkin's disease, showing Dorothy Reed cells. Low-power magnification.

Fig. 208.—High magnification of a portion of Fig. 207. Hodgkin's disease, showing Reed cells.

A case observed in 1931—man, aged 62 years.

Marked lymphatic gland enlargement in the neck and a few in the axillary region.

Blood Picture: Erythrocytes 2,130,000. Mention is made in the report that the blood cells clumped with Hayem solution but went into proper suspension with citrate solution.

Leukocytes, 5,475; Hemoglobin, 52%; Color Index, 1.2; Reticulocytes, 6.8%; Blood Platelets, 220,345.

Hemogram as follows:

Bas.	Eos.	Myel.	Juv.	Stabs		Segs.	Lymphs.	Monos.
0	2	0	2	18		29	46	3

Thick drop showed 2+ polychromasia.

Wassermann, Kolmer, Kahn, and Hecht-Gradwohl negative.

Microscopic examination of the lymphatic gland from the neck showed typical epithelioid giant cells with a few eosinophiles and a marked reaction of fibrous connective tissue. Diagnosis on this report was "typical structure of gland from Hodgkin's disease."

A case observed in the St. Louis County Hospital is recorded as follows:

Male, aged 10 years. Patient had enlargement of gland on left side of neck for six or seven years, increasing in size gradually until it is now markedly enlarged. This gland seems not to be attached to other parts of the neck, and it can be moved about under the skin. It seems to be cystic in one or two places.

There is no redness, pain, or tenderness. There are no other glands involved.

Patient had no cough, but takes cold easily. Head negative, tonsils enlarged. Heart, systemic murmur. Abdomen, spleen not palpable; no masses; no tenderness. Extremities, negative.

Reflexes, equal and active.

Patient has good appetite, but sometimes is unable to retain food.

About one and a half years ago patient had an ultraviolet ray treatment, but with no apparent improvement.

Since admittance to hospital temperature ranges from 100° to 101.6° F.; pulse ranges 118 to 132; respiration 20 to 26.

X-ray showed chronic bronchitis and cardiac hypertrophy.

Blood Picture: Red cells, 2,630,000 (clumping of red cells noted); Leukocytes, 15,600; Hemoglobin, 40%; Color Index, 0.7.

Hemogram as follows:

Bas.	Eos.	Myel.	Juv.	Stabs		Segs.	Lymphs.	Monos.
0	0	0	0	6		82	12	0

Blood Picture five days later showed: Red cells, 3,440,000; Leukocytes, 27,990; Hemoglobin, 42%; Color Index, 0.6.

Hemogram as follows:

Bas.	Eos.	Myel.	Juv.	Stabs		Segs.	Lymphs.	Monos.
0	0	0	0	8		86	5	1

NOTE.—In making the red cell count on March 14, the red cells clumped with Hayem solution but went into proper suspension with 2.5 per cent sodium citrate solution. This was noted again on March 19. However, one blood transfusion was given this patient and on the occasion of the next count of the red cells on March 24, the clumping in Hayem solution was not observed.

Microscopic sections of a lymphatic gland showed some degree of proliferation of the lymphoid cells with considerable invasion of connective tissue which has impinged upon the normal lymphoid tissue area. This obliteration is marked in certain parts of the gland. Scattered among the lymphoid cells are many large cells many times the size of the lymphocytes. Cytoplasm is clear, with irregular stainable shreds. They contain one or two nuclei which are rounded or indented. Some of these nuclei contain nucleoli. Occasionally epithelioid cells are found, the so-called Dorothy Reed cells.

Brill-Symmers Disease (Giant Follicular Lymphadenopathy)

This is a disease which involves the lymph nodes and spleen. It has been designated generalized giant lymph follicle hyperplasia of lymph nodes and spleen, generalized follicular lymphadenopathy with splenomegaly, benign lymphosarcoma, pseudoleukemia, Brill-Symmers disease, Baehr-Brill's disease.

Fig. 209.—A benign type of multiple giant follicular lymphoblastoma. (Courtesy Dr. Walter Siebert, St. Louis, Mo.)

Fig. 210.—High-power enlargement of lymphoblastoma. (Courtesy Dr. Walter Siebert, St. Louis, Mo.)

Clinically it resembles Hodgkin's disease. Microscopically, sections show a replacement of the normal architecture of lymph glands by dimensionally and numerically increased, abnormally shaped lymph follicles due to a peculiar hyperplasia of their germinal centers. Siebert¹ reported five cases. He divided these cases into two groups: (1) in which the hyperplastic follicles in the lymph nodes and spleen maintain their structural identity for a long time, or disappear temporarily, or rupture and heal; (2) in which the case may transform into (a) a polymorphous lymphosarcoma, or (b) become associated with histologic changes of Hodgkin's disease, or (c) with the changes of lymphocytic leukemia, or (d) with those of a disease with necrotic lesions, or (e) a combination of giant follicular lymphosarcoma and Hodgkin's disease which may be seen in the same lymph nodes.

¹Siebert, W. J.: Bull. St. Louis Med. Soc. 36: 415, 1942.

Clinical Symptoms.—Lymph nodes become enlarged, remaining discrete, may become as large as 10 cm. There is usually weakness, anorexia, loss in weight, and low-grade fever.

Blood Picture.—Ten per cent of the cases show a mild leukopenia, with a lymphocytosis of from 50 to 60 per cent, and a mild eosinophilia, 4 to 6 per cent. There may be a slight anemia.

Fig. 211.—Low-power view of early transformation of the giant follicular blastoma into polymorphous cell lymphosarcoma. (Courtesy Dr. Walter Siebert, St. Louis, Mo.)

Fig. 212.—High-power view of polymorphous cell lymphosarcoma arising from a giant follicular blastoma. (Courtesy Dr. Walter Siebert, St. Louis, Mo.)

The disease is important because it is likely to be confused with other conditions. Biopsy of the glands should be sufficient to clarify the situation.

Cervical Lymphadenopathy

This group of diseases is due to various causes. One may divide all lymphadenopathies, cervical or otherwise, into three groups, according to Wiseman¹: (1) those in which the predominant characteristics are significant

¹Wiseman, B. K.: Ohio M. J. 29: 364, 1933.

of malignancy; (2) those in which the reaction is like an infectious process; and (3) those which seemingly bear no relationship to either infection or neoplasm.

The first group is composed of three clinical subdivisions: (1) lymphosarcoma, including those tissues having the pathology typical of lymphocytoma, lymphoblastoma, reticulum cell sarcoma, or plasmacytoma; (2) the leukemias, comprising the chloromas, mixed-cell leukemias, leukosarcomas, pseudoleukemias, and the aleukemias as well as the pure myelocytic, lymphocytic, or monocytic leukemias; and (3) true tumor metastases in which group is included not only the cancer metastases but also the primary lymph node endotheliomas.

The second major groups, the infectious, nonmalignant lymphadenopathies, comprise four clinical types: (1) lymphatic tuberculosis, (2) syphilis, (3) simple lymphadenitis (infections of focal origin), and (4) infectious mononucleosis.

The third major group, comprising diseases which are neither infectious nor malignant, is represented by only one class, lymphadenosis, or benign hypertrophy.

Differential Diagnosis.—At this point the knowledge of the regional anatomy of the lymphatic tissues is indispensable in differential diagnosis; for instance, enlargement of the preauricular node may be due to a focus of chronic conjunctivitis. In order to make a correct diagnosis, one must consider the following points: temperature, characteristics of the nodes, splenomegaly, blood picture, and biopsy.

Fever is found only among the diseases of the infectious group.

With respect to the characteristics of the nodes, the presence or absence of pain, the distribution of the swellings, whether local or generalized, and third, the physical characteristics imparted to the palpating fingers by the diseased nodes, are points to be determined. Painful glands suggest infection, which may be inflammatory.

Distribution of the gland swellings is important. Thus, generalized adenopathy without fever is characteristic of the chronic leukemias, the afebrile stage of Hodgkin's disease, and the benign hypertrophies; if fever is present, a generalized swelling means syphilis, Hodgkin's disease, infectious mononucleosis, generalized lymphatic tuberculosis, serum sickness, or an acute phase of leukemia. Local swelling without fever suggests lymphosarcoma, tumor metastasis, lymphadenosis, tertiary syphilis, or Hodgkin's disease. Local swelling combined with pain and inflammation is nearly always indicative of local infection, either lymphatic tuberculosis or pyogenic lymphadenitis, but never of Hodgkin's disease.

Palpation gives important data. Some cases of metastatic carcinoma and some very chronic types of Hodgkin's disease show very hard and unyielding glands but many do not. Many malignant adenopathies and cases of Hodgkin's disease exhibit discrete, not fused, glands. In leukemia, the glands are always discrete and elastic to the touch. A chronic fluctuant or soft node, if painful, adherent to the skin, or showing evidence of previous sinus infection, usually means localized lymphocytic tuberculosis.

So far as enlargement of the spleen is concerned, a hard spleen extending nearly to the umbilicus with concomitant generalized adenopathy nearly always means leukemia—and the larger the spleen the more likely is the leukemia to be myelocytic in type. In Hodgkin's disease the spleen does not usually extend much below the costal border and is not palpable at all in one-half of the cases. A slightly enlarged spleen is seen in infectious mononucleosis.

The Blood Picture.—In malignant cervical adenopathies, the blood picture is normal except in those patients in an advanced stage or with leukemia. Leukocytosis with neutrophilia is strong evidence that the adenopathy in question is of infectious origin. With lymphocytosis, monocytosis, and mild anemia of the hemoglobin type, we suspect lymphatic tuberculosis; with lymphopenia, eosinophilia, and monocytosis, and usually leukopenia, with marked anemia of the red blood cell type, the blood reflects Hodgkin's disease. Normal total reds and whites, with eosinophilia and lymphocytosis, suggest syphilis; marked lymphocytosis, Rieder cells, and normal red cells suggest infectious mononucleosis. With simple pyogenic lymphadenitis, there is only a neutrophilia. Noninfectious, nonmalignant lymph gland diseases are characterized by normal total counts but relative increases in the lymphocytes. Do not confuse this group with aleukemic phases of chronic lymphocytic leukemia.

Biopsy.—Select the gland that is most likely to contain the most pathology; i.e., usually the largest gland. Remove the entire tissue, but do not cut across nor rupture the gland.

“Significant” Inguinal Lymphadenopathy—“Triangle” Adenopathy of Agress

Lymphadenopathy in the malignant lymphomata and leukemic diseases is so well known that it hardly appears necessary to elaborate on it. However, a number of years ago, we were impressed with the distribution of lymph node enlargement in the *inguinal* region in these conditions. When lymph nodes were present in the groin in the malignant lymphomata, they often extended down to the apex of Scarpa's triangle. By recurrent local usage, such nodes have taken on the designation of “triangle” adenopathy in contradistinction to “inguinal” adenopathy located in closer proximity to the inguinal ligament (Fig. 213). We have been unable to find any reference in the literature suggesting that there is any clinical significance in distribution of inguinal nodes, albeit there are general references to inguinal adenopathy in malignant disease.^{1, 2, 3} Wintrobe's¹ Fig. 197 shows this triangle adenopathy in an extreme case of “reticulum cell” sarcoma, but he makes no special point about the distribution.

In an attempt to elaborate this physical sign, we examined 494 normal and abnormal subjects for inguinal adenopathy. The examinations of all individuals in this study were carried out with the patient in the supine position. The inguinal regions were inspected with the extremities outstretched

¹Wintrobe, M. M.: *Clinical Hematology*, Philadelphia, 1952, Lea & Febiger, pp. 818, 889.

²Sugarbaker, E. D., and Craver, L. F.: *J. A. M. A.* 115: 17, 112, 1940.

³Taylor, G. W., and Nathanson, I. T.: *Lymph Node Metastases*, New York, 1942, Oxford University Press.

and on occasion adenopathy was readily visible. Following palpation in this position, the thigh was flexed and slowly abducted and adducted. This latter maneuver accentuated the boundaries of Scarpa's triangle and permitted ready palpation of the apical and deeper portions of this area. The remainder of the lower extremity, the buttocks, and the lower abdominal wall were then examined for infection, and the subject was questioned concerning infection in these regions.

Fig. 213.—Inguinal and triangle adenopathy. (Contributed by Dr. Harry Agress.)

The control group of this report consisted of 256 subjects ranging in age from 10 to 82 years. All of these patients were seen either for routine examinations or for disease processes not generally associated with lymphadenopathy. For the purpose of this study, these patients can be considered "normal." Fifty-four (21.0 per cent) of these normal subjects displayed "inguinal" adenopathy (Fig. 214 and Table 68). This category included every individual who showed even the smallest palpable node, the degree of adenopathy being almost universally of the variety familiarly noted in records as "no significant adenopathy" or "small shotty nodes." In all instances these were felt only in the immediate vicinity of the inguinal ligament and in *no case* were nodes felt *extending down to the apex of Scarpa's triangle*.

The abnormal group included 194 subjects with malignant lymphoma or leukemia. All diagnoses were confirmed by accepted standards, utilizing lymph node biopsy, blood studies, bone marrow aspiration, or autopsy. There were 78 (40.2 per cent) examples of "inguinal" adenopathy, which included adenopathy of all degrees and distribution in the groin (Table 68 and Fig. 214). This higher incidence (40.2 per cent) as compared with the normal controls (21.0 per cent) comes as no surprise. However, when this adenopathy was scrutinized as to distribution, it was found that 55 patients (28.4 per cent) had "triangle" adenopathy as compared with none in the normal con-

TABLE 68

DISEASE	TOTAL NUMBER OF CASES	INGUINAL ADENOPATHY		TRIANGLE ADENOPATHY	
		NO.	PER CENT	NO.	PER CENT

Fig. 214.—Inguinal and triangle adenopathy, normal controls and malignant lymphoma and leukemias. (Contributed by Dr. Harry Agress.)

trols. The degree of this "triangle" adenopathy was quite variable. In general, it paralleled the degree of "inguinal" enlargement, but occasionally it occurred in the absence of inguinal adenopathy or was more striking than the "inguinal" adenopathy. In two patients, "triangle" lymph node enlargement was the *only* adenopathy noted in the entire physical examination. Because we considered this adenopathy "significant," biopsy was performed, and diagnoses of malignant lymphoma were made in both instances. Generally, the degree of "triangle" adenopathy and "inguinal" adenopathy not only paralleled each other in incidence, but in various disease groups such adenopathy paralleled the occurrence of generalized adenopathy (see Table 68 and Fig. 215). For example, lymphocytic leukemia and leukosarcoma, which are usually associated with generalized lymph node enlargement, had the highest incidence of both "triangle" and "inguinal" adenopathy. On the other hand, in the acute "stem cell leukemias," where generalized adenopathy has a low incidence, both "triangle" and "inguinal" adenopathies

were minimal. Further analysis of these data failed to reveal any constant correlation between the incidence of groin adenopathy and the stage of the disease process. In general, the more advanced the disease the more striking was the adenopathy. Occasionally, "triangle" adenopathy was the initial presenting site of lymph node enlargement.

To test the validity of interpreting the significance of "triangle" adenopathy, a similar survey was made of nonmalignant diseases associated with lymphadenopathy. Twenty-four cases of acute infectious mononucleosis were studied; 9 cases (37.5 per cent) had "inguinal" adenopathy and 3 cases (12.5 per cent) showed "triangle" adenopathy (see Table 68 and Fig. 215).

Fig. 215.—Inguinal and triangle adenopathy, percentage incidence. A, Normal control; B, malignant disease group; C, lymphocytic leukemia; D, leukosarcoma; E, myelocytic leukemia; F, lymphosarcoma; G, monocytic leukemia; H, Hodgkin's disease; I, acute stem cell leukemia; J, infectious mononucleosis; K, acute infection of lower extremity. (Contributed by Dr. Harry Agress.)

No other infectious diseases associated with generalized adenopathy were seen in sufficient numbers to be statistically valid. Twenty cases of infection of the lower extremity were examined and in 50 per cent of these, there was "inguinal" node involvement on the affected side only (see Table 68 and Fig. 215). Four cases (20 per cent) of infection of the lower extremity showed "triangle" adenopathy on the involved side. In all these instances of infection of a lower extremity, the disease process was quite obvious or a history of such infection was readily obtained. On the other hand, the cases of infectious mononucleosis sometimes posed a slightly more difficult problem. However, the clinical picture together with adequate blood studies generally resolved the problem of diagnosis.

From these observations, it is concluded that when adenopathy is present at the apex of Searpa's triangle, such lymph nodes are "significantly" pathologic. Palpable "triangle" nodes should arouse a high degree of suspicion of malignant lymphoma or leukemia. Acute infectious mononucleosis and infection of the lower extremity must be ruled out. On the contrary, the absence of "triangle" adenopathy does not militate against the diagnosis of

pathologic lymph node involvement in the groin. Other enlarged nodes may be significant and should be evaluated on such features as clinical picture, size, consistency, duration, and rate of growth.

Treatment of Leukemia and Malignant Lymphomata

There is as yet no satisfactory treatment of leukemia or the malignant lymphomata, but interest is great as the tremendous amount of basic research and animal experimentation in this field bear witness. Despite the generally poor results in treatment, advances have been made that suggest the possibility of success in the future. Perhaps the most outstanding feature of present-day therapy is the attack on these diseases with the use of chemotherapeutic agents based on some new concepts.¹ Basically, this concept is that the cancer cell (leukemic or otherwise) can be regarded in principle much like invading microorganisms. These latter can be destroyed by chemotherapeutic agents while in the human host. Then why not attempt to destroy cancer cells in the same way, without injuring normal cells? The basic principles of this approach are (a) the principle of "dynamic equilibrium," and (b) that of "specific nutrition." Principle (a) fundamentally states that all cells require a constant supply of proper nutriment to survive. Principle (b) states that different cell types may have different nutritional requirements either from their external environment or within their internal mechanisms. This concept has been referred to as "the heterogeneity of nucleic acid anabolism." The researches of the Sloan-Kettering group have been directed at applying these concepts by selective feeding of modified chemical agents to cancer cells effecting a starvation of the cell particularly directed at nucleic acid metabolism. This group has repeated in tissue culture of normal and cancer cells what can be shown in bacterial cultures, namely, selective destruction of cells by chemical agents.

SubbaRow's² synthesis of folic acid (pteroylglutamic acid) and the finding that the clinical course of acute leukemia was unfavorably affected by this substance or its conjugates led Farber and his associates³ to use folic acid antagonists in the treatment of acute leukemia in children. The Sloan-Kettering group has carried on extensive animal research with these chemical compounds, as well as others, with very promising results. Using 10 different compounds on 5- to 7-day-old tumors in mice, 1,275 animals (67 per cent) out of 1,910 treated were cured. In mouse leukemia, 44 per cent cures were effected with 6 selected compounds. Amethopterin, an analogue of Aminopterin, was found 98 per cent effective against Line I mouse leukemia but effected no cures in Line I/A, a resistant strain. However, when a combination of P-165 (azaserine or O-diazoacetyl-L serine) and 6-MP (6-mercaptopurine)* was used against this resistant Line I/A strain, 98 per cent of the

mice were cured of their leukemia. These results are most encouraging in that an approach appears possible that may shed a ray of hope in the treatment of human leukemias.

To date no human cures of leukemia by chemical or other agents have been effected. The literature on the use of these agents is voluminous and has been excellently reviewed by Wright and associates.⁴ Therapy with the folic acid antagonists has been the subject of a lengthy supplement of *Blood*.⁵ Chemotherapy of leukemia, Hodgkin's disease, and related diseases based on ten years' experience has been reported by Wintrobe and his group.⁶ The folic acid antagonists which have been used in the treatment of leukemia are Aminopterin, Amethopterin, Amino-an-fol, Adenopterin, and Aminoteropterin. All of these related compounds are pteroylglutamic or pteroylaspartic acid derivatives. Farber's enthusiasm for the results achieved with these antagonists has not been shared by everyone and results from their use have varied. Whatever else may be said about these compounds, one thing stands out in our minds: hopeful events have happened in patients with acute leukemia that never happened before these agents came along. Everyone who has treated acute leukemia, especially in children, agrees that the folic acid antagonists have a profound effect on this disease, which in the past left us dismayed and hopeless as it ran its speedy course unchanged by any known form of therapy. The most striking cases are those in which the peripheral blood picture may approach normal and in which the bone marrow shows considerably diminished leukemic activity. It is claimed that in some rare cases, autopsy failed to show any evidence of leukemia. Clinically, these patients display improved vigor, require fewer transfusions, and are generally useful. These remissions may last only a few days up to many months.

When one tries to analyze statistics as to the benefits derived from folic acid antagonist therapy, there are many variables that readily account for the differences in opinion. Cases of acute leukemia are fortunately relatively rare and very few observers have had an opportunity to manage sufficiently large enough numbers of patients to make their statistics entirely acceptable. The classification of acute leukemias may vary from one group to another, which adds another variable to statistical analyses. As with all investigations and therapeutic approaches to disease, the intensity of interest and enthusiasm of the investigator is often reflected in beneficial results in patients not achieved by physicians whose interest is more casual. This not only involves more careful dosage schedules but care in general management that adds some imponderables to successful therapy.

With folic acid antagonist therapy there is no unanimity of opinion as to whether treatment should be pushed to toxicity with high dosage and a rest period, or whether modest dosage schedules should be followed intermittently, or if there should be continuous therapy. Whatever schedule is followed, leukocyte counts and the blood picture are generally helpful and necessary in

⁴Wright, C. S., Sundharagati, B., Bass, J. A., and Bunner, A. E.: *Arch. Int. Med.* **92**: 357, 1953.

⁶Wintrobe, M. M., Cartwright, G. E., Fessas, P., Haut, A., and Altman, S. J.: *Ann. Int. Med.* **41**: 447, 1954.

following these cases. In some cases the white count may return to normal or near-normal values, with disappearance or diminution of leukemic cells in the blood spread.

One of the troublesome problems in many of these patients is that leukopenia is a common accompaniment of the natural history of acute leukemia and that the blood spreads may show relatively few leukemic cells. Studies of the bone marrow in such cases show a wildly active leukemic process. Should these patients be given a leukopenia-producing agent? If so, what should determine dosage? Situations such as these appear to require more courage than scientific knowledge. When toxicity occurs, the symptoms may be more distressing than those related to the leukemia: affection of the gastrointestinal tract, with gingivitis, stomatitis, anorexia, and bloody diarrhea. Folic acid and citrovorum factor, vitamin B₁₂, antibiotics, and liver preparations have been suggested to counteract those toxic effects but have been generally ineffectual. Hemorrhagic diatheses from thrombocytopenia or ulcerations in the gastrointestinal tract present serious problems.

Another complication of therapy is resistance to certain preparations in human beings just as in the mouse experiments previously cited. Such resistance does not militate against use of other agents.

Perhaps the results with the use of folic acid antagonists can be summarized by reiterating that in some cases effects occur that have not been previously observed in acute leukemia. These favorable responses occur much more frequently in children than in adults, and their duration is variable but with no expectancy of cure. Other forms of leukemia are not favorably affected by these agents.

6-MP (6-mercaptopurine, Purinethol) is a recent antimetabolite used in the treatment of leukemia. This substance acts as a purine antagonist against certain forms of bacteria, but its mode of action in leukemia is unknown, albeit apparently in a manner different from the folic acid antagonists. Burchenal and associates⁷ have summarized their clinical evaluation of this agent in a very comprehensive review including the pharmacology, clinical results, and toxicology together with a series of representative case histories. The results appear to follow those obtained with folic acid antagonists with more strikingly beneficial results in children with acute leukemia, 15 out of 45 such cases showing good clinical and hematologic remissions and another 10 cases showing partial improvement. In adults, remissions in acute leukemia have been only occasional, and temporary remissions have occurred in some cases of chronic myelocytic leukemia. The lymphomata, including lymphocytic leukemia and lymphosarcoma, were unaffected by 6-MP. In some instances of acute leukemia in children with resistance to folic acid antagonists or to ACTH or cortisone, 6-MP proved effective in producing some degree of remission. Resistance to 6-MP develops more rapidly than with the folic acid antagonists but there apparently is no cross-resistance between the two. Toxic effects were primarily hemopoietic with leukopenia and bone marrow depression. However, there is cessation of this process on withdrawal of the drug. Gastrointestinal symptoms were generally mild and not of the

⁷Burchenal, J. H., Murphy, M. L., Ellison, R. R., Sykes, M. P., Tan, I. C., Leone, L. A., Karnofsky, D. A., Craver, L. F., Daregon, H. W., and Rhoads, C. P.: *Blood* 8: 965, 1953.

order of severity of those produced by the folic acid antagonists. Tivey and Bross⁸ summarized the results of a conference on therapy with 6-MP as follows:

Of 337 children with acute leukemia treated in thirteen clinics, 36 per cent were improved. The percentage varied from 13 per cent in one clinic to almost 70 per cent in another. Variables such as dosage schedules, terminology, and the use of other agents in conjunction with 6-MP made interpretation of the results difficult.

In this same report, there is an illuminating block chart (Table 69) showing that as new compounds become available, more children with acute leukemia survive one year or longer with treatment. Ordinarily 5 per cent survive beyond one year; with Amethopterin and cortisone, approximately 30 per cent carry on for one year or longer; and with Amethopterin, cortisone, and 6-MP, 50 per cent survive the year.

Urethane (ethyl carbamate) has been found an effective and relatively simple agent in the therapy of chronic myelocytic leukemia and in multiple myeloma. As with all the other chemotherapeutic agents, a host of papers on the subject may be found in both the domestic and foreign literature. It effects a lowering of the leukocyte count in chronic myelocytic leukemia and at times may cause some diminution in organ enlargements in this disease. Its greatest recommendation is the ease of administration (oral) and its relative lack of discomfort. Toxic symptoms, other than those related to the hemopoietic system, are relatively mild and disappear upon withdrawal of the drug. Rare instances of severe liver damage may occur. Since leukopenia and thrombocytopenia of serious proportions may occur, treatment with urethane should be monitored with frequent observations of the blood picture. When the leukocyte count reaches normal levels, dosage should be diminished or lowered. Our impression is that urethane therapy holds a position in relation to the treatment of chronic myelocytic leukemia that arsenotherapy used to hold.

Nitrogen mustard (methyl-bis [β -chloroethyl] amine hydrochloride) is the mustard gas of World War I vintage and has had its rebirth as a chemotherapeutic agent in the treatment of the malignant lymphomata, being most successful in Hodgkin's disease. The nitrogen mustards are representative of a group of antileukemic agents categorized as radiomimetic. Although the mustards have been tried in many forms of leukemia, their effectiveness has been greatest in Hodgkin's disease, some cases of generalized lymphosarcoma, and perhaps have an occasional worthy application in other selected cases. The mustards are administered intravenously and may cause severe chemical phlebitis or severe reactions at the site of administration if accidentally infiltrated into the tissues. Nausea and vomiting of a disturbing degree are frequent toxic side reactions. There is a considerable difference of opinion as to just where to place these agents in relation to roentgen radiation therapy. Generally speaking, there are few if any beneficial effects produced by the mustards that have not been produced by roentgen radiation. Relative costs do not appear a basis for choice. Although nitrogen mustard is less expensive,

⁸Tivey, H., and Bross, I.: Quoted in Progress Report VII, New York, 1954, Sloan-Kettering Institute for Cancer Research, p. 14.

it is best handled under hospitalized conditions, adding to the cost of therapy. Toxic manifestations, such as nausea and vomiting, are much more frequent with mustards than with roentgen radiation. Toxic hematologic effects, particularly thrombocytopenia and leukopenia of severe degree, are more likely to occur after therapy with the mustards than with roentgen radiation. In general, where organ enlargements, such as localized lymphadenopathy or splenomegaly of considerable proportions, are present, direct radiation is much more likely to accomplish shrinkage of these organs than are the mustards. Pruritus, which may be very distressing in Hodgkin's disease, responds favorably more frequently to mustard therapy than to radiation therapy. It is frequently claimed that when the malignant lymphomata become resistant to roentgen radiation, the disease will still react favorably to the mustards and may become radiosensitive again. For this reason alternate courses of therapy with mustards and radiation have been recommended and in some investigations simultaneous therapy with both agents has been tried.

Triethylene melamine (TEM) was the first of a group ethylenimine derivatives having nitrogen mustardlike actions. Included in this group are triethylene phosphoramidate (TEPA), triethylene thiophosphoramidate (thio-TEPA), and diethylene phosphoramidate (DEPA). The therapeutic effects with these substances are fairly similar to those seen with the nitrogen mustards, Hodgkin's disease being the most favorably affected, although some control of chronic lymphocytic and myelocytic leukemia has been effected. An advantage over the mustard therapy is that these agents may be given orally. Among the toxic effects, the most significant are related to suppression of hemopoiesis, with leukopenia and thrombocytopenia not uncommon. Cumulative toxic effects may reach serious proportions, and since there is a narrow margin of safety between desired clinical effects and toxic reactions, careful monitoring of the hematologic status of these patients is essential.

Myleran (GT 41) is one of a series of sulphonic acid and other esters which were synthesized,⁹ particularly with the idea that they might exert nitrogen mustardlike biological action. Galton¹⁰ reported on the use of this agent in leukemia and found it effective in producing remissions in chronic myelocytic leukemia. Its major field of usefulness appears to be in this form of leukemia because of its depressive action on the myeloid series. Thrombocytopenia may be an important undesirable toxic effect.

Steroid therapy in the form of cortisone or corticotropin (ACTH) has been used in selected cases of leukemia and the malignant lymphomata. One gathers the general impression that these agents are most helpful in those cases which have as an associated phenomenon some secondary immunohematologic features, such as hemolytic anemia, thrombocytopenia, or leukopenia. Consequently, these agents have not been used as primary weapons against such malignant disease but rather as adjunctive therapy along with other therapeutic approaches. Such situations arise frequently in the acute leukemias and in selected cases of the chronic leukemias and malignant lymphomata in which splenic involvement is prominent. The incidence and character of toxic effects with ACTH and cortisone are similar to those ac-

⁹Haddow, A., and Timmis, G. J.: *Lancet* 1: 207, 1953.

¹⁰Galton, D. A. G.: *Lancet* 1: 208, 1953.

companying their use in other disease processes. These include the Cushing's syndrome (acne, hirsutism, edema, moon facies, hypertension, and glycosuria), mental depression, and psychoses.

Radiation therapy "is still the sheet anchor for treating chronic leukemias"¹¹ and, we might add, the treatment of malignant lymphomata. Radiation has been used in the form of external radiation or internal radiation (radioactive isotopes). Variations in dosage schedules and methods of application are numerous, with champions representing the various schools of thought. As with many other therapeutic procedures, the enthusiasm and persistence of the therapist color his views. The end results of radiation, regardless of method, appear to be about the same insofar as longevity and relief of symptoms is concerned. Toxic symptoms of external radiation include radiation sickness, which is seldom seen with isotope therapy. On the other hand, annoying hematologic complications, such as severe leukopenia, anemia, and thrombocytopenia, are more frequent with isotope therapy than with external radiation. The shrinkage of organ enlargements, such as splenomegaly or lymphadenopathy, can be more effectively accomplished with radiation therapy than with isotopes.

The most frequently used isotope is radioactive phosphorus (P^{32}). This agent may be administered orally or intravenously. There is a period of approximately 3 to 4 weeks before therapeutic response is seen. Colloidal gold (Au^{198}) has been used in some cases of chronic myelocytic leukemia¹² and it has been tried in the treatment of effusions caused by malignant neoplasms.¹³

Radiation therapy is not used in the acute leukemias. It has a very useful place in the malignant lymphomata, with external radiation generally favored over isotope therapy.

A host of miscellaneous forms of therapy has been reported with varying results. Myelokentric and lymphokentric acids¹⁴ have been administered on the basis of the reciprocal actions of substances affecting the myelopoietic and lymphopoietic systems. Vitamin B_{12} and other hematinics have been generally found ineffective. In addition, a large number of chemicals known to produce leukopenia in animals and human beings have been given limited therapeutic trials.

Transfusions play a very important role in the management of the anemia associated with leukemia and the malignant lymphomata. The ready availability of blood has been a major factor in the rehabilitation of many of these patients, whose anemia generally does not respond to oral hematinics unless there is an associated blood loss. It is our opinion that many of the benefits of modern care of these patients can be attributed to the free use of whole blood.

Almost all of the antibiotics have been used as adjunctive therapy in the treatment of the leukemias. The display of these agents has embodied both prophylactic therapy and the treatment of actual infection. As one reads

¹¹Wright, C. S., Mabry, D. S., Carr, R. D., and Perry, A. M.: *Arch. Int. Med.* **94**: 995, 1954.

¹²Andrews, G. A., and Tyor, M. P.: *J. Lab. & Clin. Med.* **42**: 777, 1953.

¹³Andrews, G. A., Root, S. W., Kerman, H. D., and Bigelow, R. R.: *Ann. Surg.* **137**: 375, 1953.

¹⁴Turner, D. L., Miller, F. R., and Flint, J. S.: *J. Nat. Cancer Inst.* **14**: 439, 1953.

some of the literature, there is an overtone suggesting that the antibiotics might have some beneficial influence on the leukemic process other than those effects related to infection. Our experience is that, in the absence of infection, the antibiotics can play only a questionable role.

TABLE 69.—CHEMOTHERAPEUTIC AGENTS USEFUL IN TREATMENT OF NEOPLASTIC DISEASES

AGENT	AVERAGE DOSE	DISEASES BENEFITED	EFFECT OF OVERDOSAGE; COMPLICATIONS
Urethane	0.5-1.0 gm.	Multiple myeloma Myeloid proliferative dis- eases Leukemia, chronic granulocytic Polycythemia vera?	Anorexia, nausea, vomiting, olfactory disturbance Leukopenia, pancytopenia (rare) Centrilobular hepatic degen- eration and necrosis

Revised from Rundles, R. W., Barton, W. B., and Coonrad, E. V.: South. M. J. 46: 259, 1953. By permission of authors and publisher.
*Personal communication, Wayne Rundles, M.D., Duke University.

With the growing consciousness of immunohematologic mechanisms, more and more cases of leukemia and lymphomata are being considered for splenec-
tomy. The patients with secondary hemolytic anemia are the ones in whom
splenectomy has been frequently considered, especially in cases of chronic
lymphocytic leukemia. Poor results with splenectomy have been recently
reported in 5 advanced cases of Hodgkin's disease.¹⁵ It would appear that

¹⁵Sykes, M. P., Karnofsky, D. A., McNeer, G. P., and Craver, L. F.: Blood 9: 824, 1954.

unless well-proved immunohematologic mechanisms can be demonstrated in an individual case, splenectomy should not be considered. Splenectomy, when effective, affects only the abnormal immunologic process, and whatever benefits accrue to the patient are the result of such influences. The basic disease is usually unaffected or the clinical course may be precipitated into a more rapid tempo.

In the choice of treatment of any patient, a host of factors must be given consideration. Undoubtedly, the philosophy of the therapist plays a leading role in such decisions. The utter pessimism of some physicians is understandable in the light of the death sentence imposed by a diagnosis such as leukemia or malignant lymphoma. The outlook has been brightened by the well-established effects of the antimetabolites in acute leukemia, where events have taken place that were never seen before. These results have modified the views of many in the direction of achieving "control" of these diseases in somewhat the same manner as diabetes is controlled. The approach to such control in our present state of knowledge is limited to a great extent by the untoward reactions of the agents used in combating these diseases. There are many times when the natural course of the disease is better left undisturbed than overzealously treated to the point where the discomfort from the therapy far outshadows that associated with the disease process. This implies a thorough knowledge of the natural history of the disease, which may be difficult to prophesy in individual cases but has been fairly well categorized in general. Many studies on life expectancy have been published; there is no conclusive proof that life expectancy is prolonged by our present-day treatment, except perhaps in acute leukemia, especially in children. The pessimistic school has raised the question of whether such increases in prolongation of life as may occur are even worth while and point to the added mental anguish and economic strain imposed upon patients and family as sufficient reason to question the wisdom of this prolongation. Social conscience and philosophy become so inextricably enmeshed in these discussions that at times we lose sight of our position. The immature press releases of the optimistic school are as much to be abhorred as is the nihilistic approach of their opposites. There is undoubtedly a middle ground of approach in which the comfort and usefulness of the patient should be our present target of therapy. Judicious application of present technics can accomplish these aims in many cases. In the meantime the genius that will effect real cure has not been revealed to us. The furious attack on nucleic acid metabolism may or may not be the proper answer but indicates an attitude of refusal to be stifled by traditional concepts. Along with this attitude comes a ray of hopefulness that satisfactory answers may come in the not too distant future. Whence will come the prophets carrying the glad tidings remains to be seen.

HEMOSTASIS AND ABNORMALITIES OF BLOOD COAGULATION

In the normal individual, blood courses through the vascular tree in a properly fluid state, carrying a multiplicity of substances and structures. Life itself is dependent upon the complex regulatory mechanisms that maintain an

exquisite balance of all the factors which combine to make for this state of normality. A basic requirement for sustaining such a status quo is an intact vascular system, which, while maintaining its integrity, still permits selective exchanges of vital materials between the circulatory system and the tissues. Although a great deal of knowledge has been accumulated concerning capillaries, there is perhaps more information concerning their reaction to injury and in disease than answers as to why they remain intact in the normal individual. Alterations in the character of the vascular bed may occur as the result of a multiplicity of causes, involving direct and indirect assault on the vessels themselves or the contents of the vessels. The end result of such attacks may be the escape of blood from the vessels, or the closure of vessels. It is quite apparent from these remarks that the study of any patient in whom the defense mechanisms for maintaining the normal liquid state of blood in an intact vascular system have been threatened involves consideration of many factors. These might be conveniently considered under the following general headings: (1) the state of the vascular tree; (2) the state of the coagulation mechanism; (3) the status of tissues and organs related to the elaboration of elements essential to maintaining normal coagulability of blood, notably the liver, spleen, and bone marrow.

Alterations in one or in combinations of these basic states may result in either a hemorrhagic diathesis or thrombosis. The clinical results of such derangements cover the entire spectrum from mild symptomatology to fatal outcome. In the study of patients with any such symptomatology, consideration of the causes involves complete history, physical examination, and laboratory examination. As in all clinical medicine, we cannot emphasize too strongly the need for thorough history taking and physical examinations *before* rushing to the laboratory for answers to such patients' problems. This orderly procedure will often circumscribe the disease process and eliminate the necessity of costly and time-consuming laboratory tests.

The history should completely consider the family history as well as the personal history of the patient. In the hemorrhagic disease group, hemophilia is undoubtedly the outstanding example. As knowledge of the factors involved in hemostasis has grown, many other examples of hereditary disease have been uncovered. Following is a list in which heredity plays a role:*

(1) Capillary purpura due to:

Hereditary capillary fragility

(pseudohemophilia, purpura of capillary weakness, von Willebrand's disease)

Hereditary capillary telangiectasia

(Rendu-Weber-Osler disease, Goldstein's heredofamilial angiomatosis, hereditary angiomata, hereditary hemorrhagic telangiectasia)

(2) Thrombocytopenic purpura due to:

Hereditary thrombocytopenia

Thrombocytopathic purpura

(Glanzmann's thrombasthenia)

*This list is based on the recommended nomenclature published by a committee sponsored by the American Medical Association and the American Society of Clinical Pathologists (Am. J. Clin. Path. 20: 575, 1959). The designations appearing in parentheses are synonymous terms found in the literature but which this committee recommends avoiding. Minor additions to the original list have been made by the author.

(3) Plasma defects affecting coagulation due to:

Unknown causes

(hereditary thrombasthenia, Glanzmann's thrombasthenia, constitutional thrombopathy, hereditary pseudohemophilia)

. Hypoprothrombinemia, familial

Fibrinogenopenia, hereditary

Deficiency of antihemophilic globulin (AHG)

Deficiency of plasma thromboplastin component (PTC)

Deficiency of plasma thromboplastin antecedent (PTA)

Deficiency of accelerator factor

(Factor V deficiency, labile factor deficiency, plasma Ac-globulin deficiency, parahemophilia)

In the personal history of the patient suffering from one of the hemorrhagic diatheses, many possibilities of acquired disease other than obvious trauma are to be considered. For the purpose of orientation as to the multiplicity of these factors, the following list has been compiled:*

(1) Capillary purpura, due to:

Mechanical cause

Infection

(Toxic purpura, Waterhouse-Friderichsen syndrome)

Emboli

Drugs

Allergy

(Schönlein's purpura, purpura abdominalis, Henoch's purpura, anaphylactoid purpura, purpura rheumatica, peliosis rheumatica, hemorrhagic capillary toxicosis)

Metabolic disturbances

Anoxia

Vitamin deficiency

(Scorbutic purpura, rutin deficiency)

Uremia

Senility

Endocrine

Neoplasms

Leukemia

Hemorrhagic sarcoma (Kaposi's sarcoma)

(2) Thrombocytopenic purpura, due to

(Morbus maculosis hemorrhagicus, Werlhof's disease, purpura hemorrhagica, primary or essential thrombocytopenia)

Idiopathic thrombocytopenic purpura

Thrombotic thrombocytopenia (Moschcowitz's syndrome)

Thrombocytic hypoplasia from endocrine disturbance or irradiation

Drugs

Allergy

Myelophthisis from unknown cause

Infection

Splenic disease

Congestive

Lipid histiocytosis

Sarcoidosis

Tuberculosis

Neoplasm, primary or secondary

*Loc. cit. preceding page.

Leukemia

Liver disease

Acquired antibodies

(3) Plasma defects affecting coagulation, due to

Hypoprothrombinemia

Vitamin K deficiency

Of newborn (melenia neonatorum, hemophilia neonatorum, morbus hemorrhagica neonatorum)

Deficient absorption from gastrointestinal tract

Obstructive jaundice

Steatorrhea

Drugs

Liver disease (pseudohemophilia hepatica)

Drugs, particularly Dicumarol ("sweet clover disease")

Fibrinogenopenia, due to liver disease

Endogenous anticoagulant

Drugs, especially heparin

Leukemia

Radiation

Venoms of snakes

Although this list appears formidable, an adequate history oriented along these lines may be very fruitful. Wearing of tight garters or other restraining garments may be the source of mechanical purpura. At times the investigation need go no farther than observation of such patients without this apparel. The complete disappearance of symptoms on this regime is generally sufficient proof of the causal factor. The list of drugs causing either capillary damage or thrombocytopenia is a very formidable one and every new therapeutic agent should be suspect. At times the incidence of purpura is so low as to make continuation of the drug generally permissible, withdrawing its use only in affected individuals. In other instances, purpura has been so universally associated with a drug as to completely bar its clinical usefulness.

Ackroyd¹ has exhaustively reviewed the **role of drugs**, as well as allergy and infections, in the causation of purpura, and we heartily recommend reading this scholarly paper on these related subjects. Among the drugs he lists are the following: Sedormid, arsenobenzol compounds, combined bismuth and arsenic therapy, sulfonamides, bismuth, quinine, quinidine, gold, iodine compounds, chrysarobin, phenobarbitone, Aleurate, digitoxin, ergot, colloidal silver, thiourea, dinitrophenol, menthol, DDT, cosmetics, and chloramphenicol. He emphasizes that such drug idiosyncrasy results in hypersensitivity due to repeated administration and questions reports of purpura occurring with the first dose of the drug. Once such hypersensitivity has developed it may persist for many years. In order to establish a cause-and-effect relationship between drugs and purpura, Ackroyd insists that administration of the drug be followed by the hemorrhagic state. Since this was not always done in case reports in the literature, there is some question concerning the role of some drugs as the causative agents in bleeding diatheses. Ackroyd calls attention to in vitro testing of alleged offending agents in addition to repetition of test

¹Ackroyd, J. F.: *Am. J. Med.* 14: 605, 1953.

doses in suspects. He has devised a series of such in vitro tests for detecting Sedormid hypersensitivity and suggests application of the same principles wherever drug sensitivity is suspect.

When the patient's platelet count has returned to normal, Sedormid is added to a blood sample, which is then observed for platelet agglutination and lysis. Both these phenomena occur in the blood of Sedormid-hypersensitive persons whereas addition of Sedormid to the blood of normal controls shows no change. If the Sedormid and control blood preparations are allowed to stand in tubes for several hours, permitting settling of the leukocytes and erythrocytes, the supernatant fluid in the two tubes is different. The supernatant layer in the control is opalescent and slightly opaque. On the other hand, the plasma layer of the Sedormid-sensitive blood sample is clear and transparent, which Ackroyd attributes to platelet agglutination and lysis. If a solution of Sedormid is added to the blood of a Sedormid-sensitive patient, clot retraction is poor, whereas no effect on clot retraction is noted in normal controls. The addition of Sedormid in saline to platelet-rich plasma of a Sedormid-sensitive patient causes lysis and agglutination of the platelets. The addition of saline alone to such platelet preparations has no effect on the platelets. The lytic effect on platelets appears to be associated with the fixation of complement, and complement is required to produce the effect. Platelet agglutination may be observed in the absence of complement.

From these observations, Ackroyd hypothesizes that "patients who have recovered from Sedormid purpura probably have in their blood stream an antiplatelet antibody which can cause lysis of platelets rendered immunologically antigenic by union with Sedormid." More recently, Steinkamp and co-workers² have extended this concept to in vivo experiments using quinine-sensitized systems as their drug milieu. The plasma of a quinine-sensitized patient was injected into a normal volunteer subject without effect on the platelets of the recipient. If, however, a dose of quinine were given to the same normal control just prior to the administration of the plasma, a prompt and sometimes dangerous thrombocytopenia ensued.

In drug sensitization of the types mentioned above, the usual mechanism of purpura production is thrombocytopenia. In some instances, a simultaneous lowering of leukocyte count or erythrocyte count may occur. Reports of bone marrow studies in the thrombopenic states due to drugs have been quite variable, and it is difficult to draw conclusions as to what constitutes changes characteristic of drug intoxication. We have seen morphologic changes in the megakaryocytes which are generally considered "toxic" and consist of abnormal and irregular staining of the cytoplasm with accompanying vacuolization. In some cases there is very little or no apparent cytolysis with platelet formation. In other cases, there are present many more youthful forms of megakaryocytes than in normal bone marrow, suggesting a "maturation arrest" phenomenon. The incidence of such increased youthful forms varies from case to case and from time to time in an individual case. Unless frequent serial bone marrow studies are performed, this phenomenon may be missed. In general, bone marrow studies are of relatively little assistance in either the diagnosis or the management of drug sensitivity thrombocytopenia. Bone marrow studies may be helpful in doubtful cases in excluding other causes of the thrombocytopenia such as leukemia or metastatic carcinoma.

²Steinkamp, R. C., Moore, C. V., and Doubeck, W.: *J. Lab. & Clin. Med.* 18: 18, 1955.

The vascular tree in drug sensitivity shows no significant histologic abnormality and is not as severely affected as are the platelets. However, in all cases of purpura due to drug sensitization, the capillary fragility test is positive. In some cases of Sedormid-sensitive patients without thrombocytopenia, a skin patch test with Sedormid may result in petechial hemorrhages over the site of application. Ackroyd hypothesizes an antigen-antibody relationship between Sedormid and the vascular endothelium in such cases.

To this group of drugs in which hypersensitivity plays a role should be added agents which apparently exert their influence more directly on the hematopoietic system. Among the commonly used preparations of this kind are the nitrogen mustards, Myleran, and 6-mercaptopurine, all of which may produce thrombocytopenia. In these instances, hypersensitivity does not appear to play a major role. Small doses administered to patients recovering from thrombopenia do not generally invoke a drop in platelets of an appreciable degree, and when there is a fall in the platelet count it is generally proportional to the dosage of the drug used. For these reasons, such agents may be repeatedly administered for the treatment of diseases of the hemopoietic system, whereas further display of offending drugs in drug-sensitive individuals is contraindicated.

The treatment of drug-induced thrombocytopenia is nonspecific. The most important step in the management of such patients is cessation of the offending agent and instruction of the patient against the future use of the drug. Since there is a possibility of cross-sensitivity by drugs of similar chemical structure, derivatives or close chemical allies of the original drug should be avoided or used very cautiously. If the purpura is severe enough to cause appreciable anemia, repeated transfusions may be of inestimable value during the acute phase. The efficacy of cortisone or ACTH is not well defined, but in the critically ill patient we would be inclined to administer either one or both of these hormones.

Perhaps one of the most difficult decisions in some patients is that concerning splenectomy. Although a few scattered reports appear in the literature, in which splenectomy was performed, it is our impression that no group has had a sufficient number of cases to warrant a strong stand favoring splenectomy, especially when one considers the apparently high mortality in the splenectomized group of drug-induced thrombocytopenias as compared with the "idiopathic" group. Our experience, which seems to coincide with others, is that the disease in drug-sensitive individuals is fairly self-limiting *if the offending agent is removed* and that the prognosis is good. Mild or moderate cases generally recover rather rapidly and splenectomy should not even be considered for this group. Even in the severe group, splenectomy should be considered only with the gravest reservations. We have observed long-standing severe thrombocytopenic purpura in three patients treated with "depot" preparations of gold salts for rheumatoid arthritis. These patients presented the special problem of the noxious agents remaining active within their body and there was no way of removing the offender quickly. Despite their grave condition, they were treated with multiple transfusions and ultimately re-

covered. BAL (British anti-lewisite) was used as an adjunctive therapy since we were dealing with a heavy metal intoxication. The effect of BAL in these cases was questionable.

Ackroyd admirably and thoroughly presents the picture of the **Henoch-Schönlein syndrome**, pointing out that in the vast majority of cases the etiology is unknown. Although allergy is invoked as a basic mechanism of this syndrome, relatively few cases have been proved as allergies. Ackroyd lists a small proportion of cases gleaned from the literature in which foodstuffs have been implicated. Included in this list are nuts, anchovy paste, blackberries, milk, eggs, potatoes, wheat, chicken, beans, plums, pork, onions, strawberries, fish, lamb, tomato, chocolate, popcorn, rolled oats, carrots, pineapple, apple, orange, and string beans. Milk, eggs, chocolate, beans, and wheat have been the most common offenders. It is to be emphasized that these cases constitute only a small minority of the total number of Henoch-Schönlein syndrome. The purpuric lesion in this syndrome is always associated with an exanthematous lesion, whereas in other purpuras the surrounding skin is normal. Originally, this symptom complex was divided into three groups based chiefly on the predominance of symptoms; namely, (1) the purpuric group ("purpura simplex"), (2) skin and joint group ("Schönlein's purpura" or "purpura rheumatica"), and (3) skin and gastrointestinal group ("Henoch's purpura" or "purpura abdominalis"). These groupings have been found arbitrary with mixtures of the symptoms varying in degree from case to case, suggesting a syndrome rather than fixed disease entities. At the onset the skin lesions may be simple purpura or may initially begin as erythematous papules, the centers of which become purpuric. It is this purpuric aspect that may suggest a blood dyscrasia. However, coagulation studies, including platelet counts, clotting time, bleeding time, and clot retraction, are normal. Capillary fragility may be increased in some cases. These normal blood findings, coupled with clinical features of acute joint or abdominal symptoms, should serve readily to differentiate the Henoch-Schönlein syndrome from a true blood dyscrasia. Treatment for this symptom-complex is generally nonspecific. If specific foods can be implicated, these should be eliminated from the diet. ACTH therapy has been used with questionable results. As a rule, the disease is self-limiting with a good prognosis, nephritis being the most serious complication. In the visceral group, abdominal pain may be so severe as to result in unnecessary surgery. However, in rare cases submucosal hemorrhage into the intestinal tract may be of sufficient degree to cause intestinal obstruction, perforating hemorrhagic ulcers, or intussusception.

Infection may be attended by purpura. Ackroyd divides these cases into the following groups: (1) Those associated with a Henoch-Schönlein syndrome. (2) Septicemias, in which purpura is a common feature of the disease process. (3) Hemorrhagic forms of acute infections, such as secondary streptococcus septicemia. (4) Purpura fulminans, occurring chiefly in children, in which the skin only is involved by purpura and a rapidly fatal course is the rule. Fulminating infections with adrenal involvement constitute the Waterhouse-Friderichsen syndrome. (5) Miscellaneous infections in which purpura is a rare complication. Although scarlet fever is the disease in which purpura occurs most commonly, the incidence of purpura is low (0.02 to 0.03

per cent). Other infections listed are acute infectious mononucleosis, varicella, rubella, diphtheria, measles, vaccinia, infectious hepatitis, tuberculosis, malaria, brucellosis, acute mastoiditis, and acute upper respiratory infections. In most of these infections, blood studies are normal other than those changes characteristic of the infection. In some cases thrombocytopenia may occur. When splenomegaly and thrombocytopenia occur simultaneously in a disease such as acute infectious mononucleosis, the clinical picture may simulate leukemia so closely as to cause concern. Careful examination of the blood spread revealing the typical changes in the lymphocytes of infectious mononucleosis should readily distinguish the disease from leukemia. Increased capillary fragility may be present more frequently than thrombocytopenia.

To Ackroyd's list of infections noted above should be added such diseases as typhus, typhoid fever, meningococcus meningitis, and subacute bacterial endocarditis. In some of these the petechial lesions appear to be the result of vascular thrombi or emboli rather than increased capillary fragility.

The acquired metabolic disturbances associated with increased capillary fragility listed form a **miscellaneous group of purpuras** of relatively infrequent occurrence. Vitamin C deficiency results in changes in the capillary endothelium cement substance, making vessels excessively permeable. The mechanism of senile purpura is generally related to the lack of supporting structure of the skin. The purpura of nephritis is poorly understood and generally attributed to changes in capillary permeability. Of the endocrine disturbances, Cushing's syndrome has been mentioned. "David's" disease¹ has been etiologically attributed to abnormal ovarian function and is usually athrombopenic. Minot² has described recurrent purpura associated with the menstrual cycle. Injection of large amounts of estrogen into animals has resulted in thrombocytopenia; Watson³ has reported this occurrence in males receiving large doses of estrogenic hormone for prostatic carcinoma. This association of purpura and estrogen therapy is not a common occurrence in the administration of estrogens at the dosage levels used in routine therapy of the menopause.

Insofar as the history is concerned, a group of hemorrhagic disorders that may be uncovered relates to those exposed to **irradiation**. Until recent years, our concern in human beings was limited to chronic exposure to x-ray with inadequate protection. The individuals most frequently involved were professional personnel, such as physicians and technicians. Rarely, patients have been sufficiently overexposed to cause hemopoietic disturbances. Industrial exposure to radium, such as those engaged in watch-dial painting with radioactive substances, formed an interesting and unusual chapter in radiation exposure. In most of these instances, the hemopoietic disturbance was slow in appearing and had the picture of an aplastic anemia. Thrombocytopenia was only one facet of the hematologic disturbance generally attributable to bone marrow destruction or hypoplasia. Chronic exposure to radiation has been a relatively insignificant cause of thrombocytopenic purpura in clinical experiences in recent years. Any complacency that we may have developed in recent years concerning irradiation protection has blown sky high with the

¹David, W.: *Med. Klin.* 22: 1755, 1926.

³Watson, C. J.: *J. Lab. & Clin. Med.* 32: 606, 1947.

atomic bombs dropped on Japan in World War II. A vast literature concerning acute radiation effects involving total body radiation has been accumulated both experimentally and clinically. The experimental data have been more carefully controlled in the reports of Cronkite and Brecher,⁴ Allen,⁵ and Tocantins.⁶ In the discussions of these authors at the Fifth Conference on Blood Clotting and Allied Problems, the general conclusion was that bleeding diatheses accompany acute total body radiation, but are not necessarily the major cause of mortality in exposure to high magnitude acute radiation. When a hemorrhagic syndrome does occur, it is not altogether limited to thrombocytopenia and effects on the bone marrow. There occur widespread disturbances of the bone marrow. There also occur widespread disturbances of the total mechanism of hemostasis involving both the vascular tree and various complexes of the clotting mechanism.

The introduction of therapeutic radioactive isotopes has been accompanied by a new radiation hazard. This not only involves professional personnel but patients as well. From a hematologic standpoint, the personnel working with **radioactive isotopes** are exposed to the dangers of chronic radiation effect of the magnitude related to work with x-ray. Patients receiving therapeutic doses of such isotopes, on the other hand, are subject to more acute exposure schedules and the incidence of thrombocytopenia is sufficiently great to warrant consideration of this complication before embarking on such therapy. The clinical dosages of radioactive phosphorus in the treatment of polycythemia vera and the leukemias are in the range of thrombopenia production. Generally, the thrombocytopenia appears from 4 to 5 weeks after administration and is symptomatically mild. However, bleeding may reach sufficient proportions for transfusion therapy. In most instances, the platelet count returns to normal after a period of weeks but may persist for months. In some instances of leukemia it is impossible to decide whether persistent thrombocytopenia is a complication of therapy or of the disease. At times one may be faced with the decision of treating the leukemic patient who already has thrombocytopenia with radioactive isotope. The resolution of this dilemma is generally based more on philosophy than science. Radioactive gold salts in therapeutic dosages may also result in thrombopenic states. Radioactive iodine in the usual therapeutic dose for the treatment of hyperthyroidism is not accompanied by a hematologic change. Tracer doses of many tagged substances, such as iron, cobalt, iodine, chromium, phosphorus, and iodine, are not attended by significant changes in the vascular tree or hematopoietic system.

In the **personal history** of any patient with a hemorrhagic diathesis, questioning relative to the gastrointestinal tract, biliary system, and the liver is important. Chronic diarrhea, such as occurs in sprue, may result in poor absorption of **vitamin K**. A history of jaundice with clay-colored stools should suggest obstruction of the biliary tract with resultant vitamin K deficiency. Liver disease may be difficult to elicit in the history but history of exposure to hepatotoxic substances may be helpful, as, for example, **carbon tetrachloride** acci-

⁴Cronkite, E. P., and Brecher, G.: *Blood Clotting and Allied Disorders*, New York, 1952, Josiah Macy, Jr. Foundation, pp. 171-212.

⁵Allen, J. G.: *Ibid.*, pp. 213-246.

⁶Tocantins, L. M.: *Ibid.*, pp. 247-279.

dentally inhaled in several ways. We have seen cases resulting from the escape of this agent from fire extinguishers. In one instance, the patient used a fire extinguisher in a closed basement. In another instance, the driver of an Army vehicle was intoxicated by carbon tetrachloride escaping from an extinguisher under the driver's seat of his car. Carbon tetrachloride poisoning has been observed in persons engaged in the cleaning of clothes. Phosphorus and chloroform poisoning may result in acute hepatitis with attendant liver damage.

Acute liver disease, in the form of **virus hepatitis** or **homologous serum jaundice**, may follow injections with improperly sterilized needles or syringes, transfusions of whole blood or plasma, or the administration of yellow fever vaccine. It is well to remember that the latent period between the injection and the development of acute liver disease may be several months. In all these instances of acute hepatocellular damage, capillary fragility may be increased; platelets are generally normal but other elements necessary for coagulation are diminished (usually plasma components).*

Physical examination of the patient with hemorrhagic disease should be thorough. Examination of the skin for purpura or petechiae should be performed in a good light. Purpura occurring at sites not subject to trauma should arouse suspicion of a hemorrhagic tendency. Petechiae arranged in linear fashion suggest mechanical origins, such as tight belts, brassières, corsets, girdles, arm bands, stocking garters. Such linear arrangement should also suggest self-inflicted mechanical trauma. The occurrence of numerous telangiectasia suggests the possibility of a hereditary form of capillary fragility. Attention is called to possible bleeding from such telangiectases in the gastrointestinal tract. In such instances, skin telangiectases may suggest this possibility.

The mucous membranes are often the sight of petechial hemorrhages and include any mucous membrane that can be visualized. Good lighting is important in this search. In Negroes, the mucous membranes may be the only visible site of abnormal bleeding. The conjunctivae of the eyes and the buccal mucosa are readily visible. Nasal examination for petechiae should be performed with the aid of a nasal speculum and a head mirror. Proctoscopy and vaginal speculum examinations may reveal mucous membrane petechiae. Funduscopic examination should be included in a search for petechiae.

Jaundice of the skin, sclerae, or mucous membrane should direct attention to the liver and biliary system.

Examination of the **gums** revealing marked thickening, pallor, and ready bleeding on manipulation is suggestive of leukemic disease.

Adenopathy of general distribution arouses the suspicion of malignant lymphoma or leukemia. In this connection it has been our experience that inguinal lymphadenopathy extending to the apex of Scarpa's triangle is particularly significant. This "triangle adenopathy," as we have come to call it, is a helpful diagnostic sign when recent regional infection is ruled out. Its presence bilaterally should always arouse the suspicion of malignant lymphoma.

*Refer to pages 565, 1185, and 1725 for further information on the transmittance of viral hepatitis.

Splenomegaly will direct attention to this organ system as the reflection of possible blood dyscrasia. However, the absence of splenic enlargement should not be a deterrent in pursuing such a diagnosis. Many cases of thrombocytopenic purpura display no splenomegaly. The diseases associated with hereditary plasma defects of coagulation, such as hemophilia, fail to show organ enlargement. Splenic enlargement is not particularly striking in affections such as tuberculosis and sarcoidosis. The spleen may be fairly large in such primary neoplasms as lymphosarcoma. In the chronic leukemias such as chronic myelocytic and chronic lymphocytic leukemia, splenomegaly is usually prominent and may reach tremendous proportions. However, in the acute leukemias, where thrombopenia is generally more striking than in the chronic leukemias, splenomegaly may be either absent or negligible.

Hepatomegaly may reflect primary liver disease, such as hepatitis, cirrhosis, or carcinoma. On the other hand, hepatomegaly may also reflect systemic disease, such as leukemia. In general, chronic leukemia is associated with a higher incidence and greater degree of hepatomegaly than acute leukemic disease.

A combination of hepatosplenomegaly suggests chronic leukemia, as well as portal hypertension syndromes. In this regard, hepatosplenomegaly should suggest the group of "hypersplenisms" in which thrombocytopenia often is a feature.

Cardiac examination revealing murmurs may suggest the possibility of bacterial endocarditis.

The presence of **acute joint involvement** may suggest the Henoch-Schönlein syndrome or acute rheumatic fever. Chronic joint involvement may be remindful of lupus erythematosus disseminata, which has been attended by purpura at times.

Abnormal neurological findings will parallel the site and extent of central nervous system hemorrhage. We have observed subarachnoid hemorrhage as the only presenting clinical picture in a case of thrombocytopenic purpura.

On rectal examination, the finding of tarry stool on the examining glove is indicative of **gastrointestinal bleeding**. This blood loss may or may not be associated with a hemorrhagic diathesis.

HEMORRHAGIC DIATHESES

Purpura

Purpura is characterized by hemorrhagic discoloration under the skin without apparent reason. These discolorations may be small, when they are called "petechiae," or large, when they are called "ecchymoses" or "vibices." These spots may appear temporarily, at intervals, or as a chronic condition. We have a simple condition called "purpura simplex" or a very serious condition called "purpura fulminans." The severe cases are usually associated with spontaneous or easily induced uncontrollable internal or external hemorrhages, and the condition is known as "purpura hemorrhagica."

Purpuric cases may be separated hematologically and clinically into two groups: one, which bears a close relationship to all kinds of infectious con-

TABLE 71.—SUMMARY OF DIAGNOSTIC FACTS IN PURPURIC DISEASES

NATURE	ATHROMBOPENIC PUR- PURA	THROMBOPENIC PURPURA (WERLHOF)	HEMOPHILIA
	VASCULAR INJURY	LACK OF BLOOD PLATE- LETS	DISTURBED COAGULATION
Etiology	Infections, anaphylactoid conditions (serum dis- ease, rheumatic condi- tions, etc.)	According to Frank "es- sential," or constitu- tional reactions in la- tent infections, etc., also associated with leucemias, osteosclero- sis, endocrine disor- ders, etc.	Congenital, confined al- most exclusively to men, transmitted by apparently healthy women, aggravated by familial tendency (families subject to hemophilia).
Blood find- ings	Coagulation normal, sometimes shortened. Normal or somewhat extended time of bleed- ing. Blood platelets normal, increased, or slightly decreased. Slightly infectious leu- kocytic findings. Later anemia.	Coagulation normal, re- tractability absent, time of bleeding much prolonged. Blood platelets much de- creased or absent. Sometimes infectious leukocytic findings. After unfavorable course, severe aplastic anemia.	Coagulation prolonged in various degrees. Time of bleeding often de- creased. Blood plate- lets normal. Leuko- cytes normal, or lymphocytosis.
Clinical	Purpura-exanthemata, hemorrhages from gums, tissue hemor- rhages. Least harm- ful course, seldom ag- onal.	Purpura-exanthemata (often greatly ex- tended) hemorrhages of mucous membrane, intestinal hemorrhages, etc., acute or chronic, benign or foudroyant- malignant course. Fre- quently splenic tumors.	Sudden hemorrhages from small or internal wounds. Blood effu- sions into the joint. Periodically increased. Often fatal hemor- rhages from slightest cause.
Therapy	Directed, if possible, against etiology; oth- erwise symptomatic. Cortisone and ACTH	Symptomatic, blood transfusion, or roent- gen ray treatment of spleen. Finally sple- nectomy. Vitamins are recommended. Cortisone and ACTH (with modifications)	Blood, fresh plasma, or antihemophilic globu- lin.

Schilling: "The Blood Picture" (with modifications).

ditions, or which has an infectious character, with fever, erythemas, edema, intestinal conditions, nephritis, and neuritis. This has been called "anaphylactoid purpura" of Glanzmann, with many clinical subvarieties. The other type is idiopathic without fever and is known as "morbus maculosus werlhofi." It may be acute periodic, or chronic, or it may be a symptomatic accompaniment of a severe blood disease.

Another classification of the hemorrhagic states based on the familial hemorrhagic tendency, the physical signs, and the abnormalities of the blood has been suggested by Mettier.*

It is to be noted that the actual cause of platelet deficiency in a given patient may be undetermined. Therefore, these cases are called idiopathic or essential thrombocytopenia. Certain investigators believe that the spleen is responsible for the platelet deficiency by actually destroying these elements of the blood,¹ by removing them by phagocytosis, or through some regulatory influence exerted on the megakaryocytes in the bone marrow.† Others‡ believe that severe bleeding from the mucous membranes may be associated with a deficiency of ovarian hormone and concomitantly with a reduction in the circulating platelets. See section on Immunohematology for further comments, pages 539 ff.

The Werlhof group shows a marked decrease in blood platelets, or the "essential thrombopenia" of E. Frank. Forty thousand blood platelets are estimated as the clinical limit of the hemorrhages; purpuric bleedings may appear below this number, for the reason that the mechanical element resident in the thromboplastic platelets and the consequent retractability of the coagulum are not present to close the wound. Vascular injury, however, is considered essential for the existence of this condition.

The bone marrow in essential purpura has been studied with the end in view of finding the cause of this condition in that organ. There are two theories regarding this: one by Frank,² who claims that the fault is in the bone marrow; one by Kaznelson,³ that it lies elsewhere. Lawrence and Knutti⁴ reported bone marrow studies on a number of these cases and found that in two cases there were diminished numbers of megakaryocytes in the bone marrow; in other cases they found a perfectly normal bone marrow. These results indicate that there are probably two types of this disease, one due to bone marrow disturbance, the other due to some other condition.

Purpura is related to the hemorrhagic diatheses found in avitaminoses, infectious and toxic-vascular conditions, and serum disease, and it is also related to constitutional conditions. It appears to have some relationship to real hemophilia which is a familial constitutional condition, seen especially in men, but transmitted by apparently healthy mothers.

The Megakaryocytes in Idiopathic Thrombocytopenic Purpura, a Form of Hypersplenism

Dameshek and Miller⁴ reported their results in a study of idiopathic thrombocytopenic purpura in special relationship to the megakaryocytes.

Method.—

The peripheral platelet count was made by the indirect or wet film technic of Dameshek,⁵ using an isotonic aqueous solution of sodium citrate containing brilliant cresyl blue. The normal platelet count by this method ranges from 400,000 to 900,000 per cubic millimeter, with an average normal count of about 600,000 per cubic millimeter.

Sternal puncture was performed in these cases by the introduction of a simple sternal puncture needle through the anterior lamella and into the marrow space, at a point on the sternum between the third and fourth intercostal spaces. Drops of aspirated material were immediately placed, without the further use of anticoagulant or other material, on carefully cleansed new glass slides and gently spread with minimum pressure by means of another slide. The preparations were allowed to dry in the air and were stained first with Wright stain, then with Giemsa stain, following which coverslips mounted in balsam were affixed.

For making the megakaryocyte counts, a rectangle was cut out and placed over the slide to be studied. The megakaryocytes in this area, containing approximately 20,000 oil immersion fields, were counted and expressed in terms of a million nucleated cells. At least one-half million nucleated red cells were counted, the count being facilitated by first accurately enumerating the nucleated red cells in 20 oil immersion fields.

The differential count of the megakaryocytes can be easy or quite difficult. The typical huge adult forms are readily defined, but recognition of their precursors requires much patience and study. The predominant mode of origin of the megakaryocyte is probably from a stem cell or megakaryoblast, which in turn probably originates from the pluripotential histiocyte or hemohistioblast.

For a description of the various types of megakaryocytes, refer to pages 645 and 646.

Dameshek and Miller concluded as follows regarding megakaryocytes in thrombocytopenic purpura:

The megakaryocytes of the sternal bone marrow at biopsy were studied in 11 cases of idiopathic thrombocytopenic purpura and compared with those of 10 normal cases, 5 of thrombocytopenic purpura associated with various types of splenomegaly, and of a large group of miscellaneous hematologic conditions, including leukemia, associated with a reduction in platelets.

Megakaryocyte counts expressed in terms of a million nucleated red cells and differential counts of megakaryocytes were performed. The megakaryocytes were classified as megakaryoblasts, promegakaryocytes, and mature forms, and were further subdivided into those showing granularity, platelet production, degenerated forms, and mitoses.

⁴Dameshek, W., and Miller, E. B.: *Blood* 1: 1, 27-49, Jan., 1946.

⁵Dameshek, W.: *Arch. Int. Med.* 50: 579-89, 1932.

In the *normal cases*, not more than 300 megakaryocytes per million nucleated red cells were present, and an average of 68.6 per cent showed platelet production.

In *acute idiopathic thrombocytopenic purpura*, although the platelets in the circulating blood were rare, megakaryocytes were increased, being present in a proportion of 366 to 743 per million nucleated red cells. Platelet production was, however, greatly diminished and found in only 8 to 19 per cent of all megakaryocytes. Following splenectomy, there was a striking increase in platelet production, which was now present in 69 to 85 per cent of all cells; the large masses of new platelets in the marrow were often very striking.

In *chronic idiopathic thrombocytopenic purpura*, the megakaryocytes were considerably increased over normal values, but showed great diminution in platelet production; following splenectomy, extreme degrees of platelet production from megakaryocytes took place.

In *splenomegaly of nonleukemic origin* (cirrhosis, splenic vein thrombosis, Gaucher's disease, Felty's syndrome), the megakaryocytes were somewhat increased, but platelet production was normal.

In *aplastic anemia, lymphosarcoma, acute leukemia*, and other diseases invading or destroying the bone marrow, the megakaryocytes were conspicuously reduced, the few remaining cells present being of normal morphology.

Finding of increased megakaryocytes and greatly diminished platelet production in the marrow before splenectomy and the striking increase in platelet production after splenectomy indicate a definite pathogenetic relationship of the spleen to the disease. Idiopathic thrombocytopenic purpura is probably a form of hypersplenism (splenic thrombopenia) in which, through a possible hormonal mechanism, the megakaryocytes of the bone marrow are inhibited from normal platelet production and delivery.

The marrow findings in idiopathic thrombocytopenic purpura are sufficiently characteristic to be of diagnostic value in differentiating the disease from leukemia and other conditions associated with a low blood platelet count.

Hemophilia

Not too many years ago, most of us had the impression that we fairly well knew the classical disease, hemophilia, as an entity occurring only in males and transmitted through females as a recessive sex-linked Mendelian characteristic. The abnormal bleeding tendency was known from the early days of the Hebrews who recognized its occurrence after circumcisions, and more recent history has been enlivened by the occurrence of hemophilia in the royal families of Europe. Within medical circles, the abnormally prolonged clotting time of hemophilic blood was well known and the therapeutic value of blood transfusions well established.

Any complacency about our knowledge of hemophilia has been fervently shaken by the coagulationists. This state of affairs has come about chiefly through recent advances in knowledge of the factors involved in blood coagulation. Hemophilia is no longer a simple disease and there is some ques-

tion, even in the minds of experts, as to just what the disease is. Dameshek¹ has collected the views of outstanding experts in the field in an attempt to answer this question.^{2, 3, 4, 5, 6, 7, 8, 9, 10}

As might be expected, there are the same differences of opinion about defining hemophilia as there are concerning nomenclature and theories of blood coagulation. The center of the controversy is the nature of the plasma and platelet factors, excluding calcium, which take part in the conversion of prothrombin to thrombin. A brief glance at the theories of blood coagulation in this area readily reveals many, but not all, of the differences. We heartily recommend reading this symposium of Dameshek as an enlightening (or perplexing) presentation of how utterly stirred up the concept of hemophilia has become.

Whereas in times past, our clinical concern about hemophiliacs was limited to males, we now must consider both male and female bleeders as possible hemophiliacs. Hereditary patterns are being found in the various newly described forms of hemophilia or hemophilia-like diseases as was true of the classical disease. However, acquired defects of clot-promoting factors have been recognized in syndromes simulating hemophilia.

The laboratory diagnosis of hemophilia traditionally rested on a prolonged clotting time. This is no longer true. Although most of the hemophilia-like diseases may have a prolonged clotting time, many instances with a normal coagulation time are being uncovered. Today, in the study of any patient with a bleeding diathesis *not otherwise explained*, one must pursue a plasma defect or defects as possible causes of the disease. There are many tests of varying complexity which can help delineate these defects. Some of these have been elaborated in the section on technic and others will be mentioned here briefly in the following outline:

1. The Quick prothrombin consumption time or the serum prothrombin time. Hemophiliacs show a very short (± 10 seconds) time. Hemophilia-like states may show a *shortened* or almost *normal time*. This test is nonspecific insofar as the plasma factors are concerned.

2. Standard prothrombin activity tests, e.g., Quick one-stage or modifications thereof, show normal times in classical hemophilia but may be abnormal in some of the hemophilia-like diseases.

3. Owren technics for specific factors, such as prothrombin, proconvertin, and proaccelerin, demonstrate specific defects in hemophilia or hemophilia-like disease. It was by the use of such technics that Owren discovered parahemophilia (or factor V) deficiency.

¹⁰Pavlovsky, A.: *Blood* 11: 291, 1954.

4. Thromboplastin generation test¹ is helpful in distinguishing and assaying various components of the thromboplastin-producing system.

5. Antihemophilic globulin (AHG) assay.² This test measures the specific defect in hemophilia and is useful in detecting latent subclinical cases. Normal AHG assays at 100 per cent, whereas classical hemophilia assays at 0 per cent, moderate hemophilia less than 3 per cent, mild hemophilia 16 per cent, and subhemophilia 33 per cent.

6. The partial thromboplastin test (PTT). This is a screening procedure in which the plasma of patients with hemophilia and hemophilia-like disease may be brought under scrutiny. The authors² have hypothesized the following diagnostic groups: hemophilia, hemophilioid state A, hemophilioid state B, hemophilioid state C, and hemophilioid state D. In all of these the routine PTT gives a prolonged time. However, if equal parts of fresh normal barium-sulphate-treated plasma are added to the test plasma, the results aid in differentiation of the states. With such "fortified" plasmas, in hemophilia and hemophilioid state A the partial thromboplastin time returns to normal but in hemophilioid states B, C, or D, the partial thromboplastin time remains prolonged.

These authors have further elaborated their detection and separation system by making standard prothrombin time determinations on untreated plasma and fortified plasma (see Table 72).

TABLE 72

PROTHROMBIN TIME		
	UNTREATED PLASMA	"FORTIFIED" PLASMA
Hemophilia	Normal	Normal
Hemophilioid state A	Prolonged	Normal
Hemophilioid state B	Prolonged	Prolonged
Hemophilioid state C or D	Normal	Normal

7. Matching experiments. The basic principle of such tests is determining whether mixing the blood of one individual and that of another corrects a known defect. Such matching experiments originally aided in delineating true hemophilia from some of the subvarieties. It was found that in these subgroups, the patients' blood would correct the defect in hemophilia in the same manner as normal blood. Since then, this procedure has become standard practice in the study of hemophilia and related disorders. This technic is limited to separating the entities but does not delineate the specific deficiency. However, an understanding of such matching experiments is helpful in determining therapy. As an example, classical hemophilia will respond to concentrated antihemophilic globulin administration but other coagulation factor deficiency diseases will not respond favorably.

A typical series of such matching experiments may be found in the paper by Brinkhous and associates.³

One of the difficulties in matching experiments has been the need for blood from a patient with the deficiency of plasma factor. As the various

¹Biggs, R., and Douglas, A. S.: *J. Clin. Path.* 6: 23, 1953.
²Brinkhous, K. M., Langdell, R. D., Penick, G. D., and Graham, J. B.: *J. A. M. A.* 154: 481, 1954.
³Brinkhous and others: *J. A. M. A.* 154: 481, 1954.

factors become elaborated, their reproduction in the test tube is becoming more frequent, making such experiments available to more observers. Ideally, the isolation and purification of factors by physical and chemical means would help considerably. Such isolation is understandably difficult when one considers the complexity of the coagulation mechanism.

TABLE 73.—SUMMARY OF CLINICAL AND CLOTTING CHARACTERISTICS OF AHG, PTC, AND PTA DEFICIENCIES*

	ANTIHEMOPHILIC GLOBULIN (AHG) DEFICIENCY	PLASMA THROMBO- PLASTIN COMPONENT (PTC) DEFICIENCY	PLASMA THROMBO- PLASTIN ANTECEDENT (PTA) DEFICIENCY
Sex	Male (female very rarely)	Male	Male and female
Hereditary pattern	Sex-linked, recessive trait carried by female, transmitted to male	Similar to AHG deficiency	Not sex-linked, transmitted to male and female by female and probably male carriers
Pattern of hemorrhage: Degree Sites	Depends upon clotting time and the degree of the clotting defect		
	Slight to very severe Joints frequent, follows trauma and any operative procedure	Slight to moderately severe Joints sometimes involved, follows trauma and operative procedures	Slight to moderate Joints rarely involved, most usually follows minor surgical procedures as tonsillectomy, tooth extraction
Clotting time	Normal to over 1 hour	Normal to about 60 minutes	Normal to 30 minutes
Clotting defect corrected by:			
Normal plasma	Yes	Yes	Yes
Normal BaSO ₄ -treated plasma	Yes	No	Yes
Normal serum	No	Yes	Yes
Fraction I	Yes	No	No
Normal BaSO ₄ -treated serum	No	No	Yes
Other findings	Normal values—platelet count, prothrombin time, clot retraction Usually normal—bleeding time, tourniquet test Abnormal (degree related to the extent of the deficiency)—heparin clotting time, serum prothrombin time, recalcified clotting time of slowly and rapidly centrifuged plasma, thromboplastin generation		

*From Rosenthal, R. L.: *Am. J. Med.* 17: 57, 1954. By permission of author and publisher.

As a result of studies such as those mentioned have come such names as Christmas disease,¹ parahemophilia,² hemophilioid states A, B, C, D,³ PTC,⁴ plasma thromboplastin antecedent (PTA) deficiency.⁵ In addition, there have been designations of various factor deficiencies by number, such as factor V, VI, or VII deficiencies. There is no unanimity of opinion as to which system of nomenclature to adopt and often there is some question as to whether or not authors using different terminology are discussing the same syndrome.

Rosenthal⁶ presents an enlightening article on the clinical, laboratory, and hereditary patterns of this group of diseases. Through his permission and

that of his publisher, we reproduce a table from this communication which presents an excellent bird's-eye view of plasma factor deficiencies, Table 73.

Whatever else may be said about these new entities, there is no question that this elaboration has added considerably to knowledge related to the coagulation mechanism.

BONE MARROW STUDIES

Many of the hematologic observations which Schilling and other modern hematologists have made, and are now making, are based upon bone marrow studies. In all uncertain cases of blood diagnosis, it is well to obtain some of the bone marrow for diagnostic examination.

In the human adult the bone marrow of the long bones is yellow; the marrow is pink **at birth**. In the early years, say about **seven years**, fat in small quantities appears; between **twelve** and **fourteen years**, a visible patch of yellow appears in the middle of the femur which increases until there is only a small patch of pink marrow near the end of the diaphysis in the **adult**. The same phenomenon takes place in the tibia, ulna, radius, humerus, and fibula. The only red marrow which persists in the adult is to be found in the bones of the skull, ribs, vertebra, sternum, and the innominate bones. Bone marrow studies, therefore, are most conveniently made from the adult sternum.

The bone marrow in infants shows many immature cells. In the **six months' fetus** the red cells make up three-quarters of the total; **at eight months**, nine-tenths; and **at term**, the red and white cells are equal. Latimer and Mayerhoff found fetal marrow containing 2 to 22 per cent granulocytes. Doan and Zerfas state that during the first year of life the marrow contains 4 to 20 per cent lymphocytes. In embryonic life the ratio of erythroid to myeloid elements is 100 to 0. In adults, it is 1 to 3. Since the red bone marrow of newborn children contains many more immature cells than adult bone marrow, it is easy to understand the ready appearance of immature cells in the circulating blood of an infant following slight stimuli. In children, the number of cells in the bone marrow varies from 270,000 to 1,568,000 per c.c. In adults we find in the total bone marrow volume of 1,500 c.c. in the human body that the myeloid elements outnumber the erythroid elements 3 to 1; most of the myeloid cells, 85 per cent, are the myelocytic cells with their full quota of granules. There is a diurnal variation in leukocytes with an afternoon and midnight rise. The bone marrow delivers granulocytes, myelocytes, juveniles, and "stabs" hourly, but especially at the interval at which the leukocytes in the blood stream are increased. The maturation time from myelocytes to more mature forms is probably from forty-five minutes to two and one-half hours. One per cent of the bone marrow elements are megakaryocytes. According to Wright, these constitute the origin of blood platelets, but according to Schilling's ideas, blood platelets do not come from megakaryocytes but are extruded remnants of nuclei of red blood cells. In bone marrow, 70 per cent of the total erythroid cells are normoblasts; erythroblasts, 26 to 30 per cent; proerythroblasts, 1 to 4; and megaloblasts, 0.01 to 0.04. According to Schilling, the megaloblasts represent a stage in the development of the red cells, but according to Ferrata and Michaelson,

the megaloblast is present in the bone marrow only in cases of pernicious anemia. They do state, however, that the cell which is sometimes mistaken for the megaloblast is in reality the proerythroblast. Sabin and Doan corroborate Schilling's claim that the megaloblast is present in normal bone marrow, but only in very small numbers.

Fig. 216.—Normal bone marrow. Note lack of crowding of cells and the presence of fat. (×950.)

Reticulated red cells and normoblasts are released into the blood stream at regular intervals; the red cell count varies about 1,000,000 per cu. mm. per day. The high point of bone marrow delivery is in the morning and afternoon, not afternoon and midnight, as is the case with the white blood cells.

Summary of Normal Bone Marrow Findings

What is the normal cellular content of the bone marrow? We must assume, first, that under normal conditions, myelopoiesis and erythropoiesis are confined to the bone marrow. Lymphocytopoiesis normally does not seem to be confined to the bone marrow. The investigations of Askanazy, Oehme, von Fischer, and others showed that there are fully developed lymph follicles in the bone marrow in a large number of cases. Under normal conditions, however, lymphocytopoiesis seems to have no connection with either erythropoiesis or myelopoiesis although there is no objective hematologic proof of this. The Schilling followers do not believe that monocytopenia is connected with bone marrow function. Monocytes are seen in very few numbers in bone marrow according to Schilling, Sabin, and others. Yamamoto and Schilling¹ have shown in man and in animals that the composition of different parts of the marrow is practically the same on the same occasion in the same individual. In a few cases a peripheral eosinophilia occurred which was accompanied by an increase in the proeosinophiles in the bone marrow. On the other hand abnormally low

*From Nordensen, *Studies on Bone Marrow from Sternal Puncture*, Generalstabens Litografiska Anstalts Förlag, Stockholm.

numbers of peripheral eosinophiles were not represented by low values in the marrow. According to these authors parallelism does not exist between peripheral and bone marrow eosinophilia. Homma² found a constant bone marrow eosinophilia with an elevation in the number of peripheral eosinophiles. But conversely there may be normal or somewhat increased numbers of eosinophiles in the bone marrow in spite of peripheral decreased number of eosinophiles. Magne, in his work entitled "La Grande Eosinophilie Sanguine" (Thèse, Lyon, 1933), substantially is in accord with Homma. Barta found that the effect of toxin on eosinophiles is exerted on the fully developed cells which have wandered out and not on the young forms in the marrow which explains the peripheral decreased number of eosinophiles without a corresponding decrease in the eosinophiles of the marrow. Table 74 from "Studies on Bone Marrow From Sternal Puncture" by Nils Göran Norden-son, published by Generalstabens Litografiska Anstalts Förlag, Stockholm, gives the composition of bone marrow according to a number of authorities.

Holmes and Broun³ call attention to the mitotic divisions of cells in the bone marrow spreads made by them as being limited to an intensely basophilic cell which varies in morphology from both the typical myeloblast and the typical megaloblast. They have called this cell the primitive cell in their differential counts. They occasionally noted mitotic division in hemoglobin-containing erythroblasts. **Differential counts** by these writers of **bone marrow elements** in seven cases with normal peripheral blood pictures were as follows: myeloblasts 2.4 per cent; myelocytes 7 per cent; juveniles, 6.7 per cent; "stabs" 14 per cent; II segmented neutrophils 10 per cent; III segmented neutrophils 6.3 per cent; IV, V, etc., segmented neutrophils 1.1 per cent; eosinophiles 1 per cent; basophiles 0.3 per cent; monocytes and reticuloendothelial elements 9 per cent; lymphoid cells 24.9 per cent; megaloblasts 5.2 per cent; normoblasts 6.9 per cent; primitive cells 2.6 per cent. These findings agree rather closely with those of Arinkin⁴ on similar types of cases.

It is interesting to note that the high percentage of immature granulocytes in their counts confirms the concept of Arneth and Schilling that the neutrophilic nucleus changes progressively with age from the round to the segmented form. The high percentage of juveniles and stabs confirms the idea that these are "young" granulocytes.

An examination of Table 73 and similar tables in other publications reveals wide variations in opinions on the relative percentages of various cells, and raises some question as to the value of doing differential counts routinely on bone marrows. We are inclined to agree with Israels⁵ that "the variability of the normal bone marrow means, in effect, that only gross differences can be taken to indicate pathological change, and this in turn raises a question of whether it is worth while to undertake, in every case, the time-consuming differential count . . . this practice has now been given up for a 'qualitative assessment' in all except the most difficult cases, or in research studies. Such

a qualitative assessment is adequate for diagnosis in most intance, and gives a far clearer idea of the overall marrow picture than does a row of figures, especially since few physicians or pathologists carry the normal figures around with them.” We have used an assessment type of reporting clinical marrow aspirations, and include the following data in such reports:

Cellularity—“normal,” “increased,” or “decreased.”

Predominant cell type—normally this should be members of the myelocytic series.

Myelocytic series—normally shows predominance of older forms, e.g., stabs and segments, with a gradual diminution to myeloblasts. If a left shift is present, comment is made on the degree. Qualitative changes in the cells of this series are described, if present. Such changes include toxic granules and abnormal forms. The myeloid-erythroid ratio is estimated.

Erythrocytic series—normally shows predominance of older forms, e.g., orthochromic normoblasts with a scattering of younger forms. If a shift has occurred to younger members of this series, its degree is appraised and reported. The type of erythropoiesis is described, e.g., “definitive” (as in normal red blood cell development) or “primitive” type (as in pernicious anemia and some other markedly pathologic states). Qualitative changes, indicating pathologic erythropoiesis, are noted. These include marked poikilocytosis (poikilocytes, spherocytes, target cells), anisocytosis, basophilic stippling, abnormalities of nuclear morphology (karyorrhesis, karyolysis), and abnormal relationships of nucleus to cell size.

Lymphocytic series—normally less than 10%. Quantitative or qualitative changes in these cells are noted.

Megakaryocytes—normally readily found, especially in the thin and thick ends of spreads. They tend to be fewer in the middle of spreads. Qualitative changes, such as cytolysis with degree of platelet formation, are described.

Other cells, such as fat, reticuloendothelial cells, and “cells foreign to normal bone marrow (tumor cells)” are noted.

Mitoses are noted as to frequency, and comment is made as to whether mitotic figures are normal or abnormal in appearance.

TABLE 75.—BONE MARROW: GENERAL COMPARISON OF SPREADS AND SECTIONS

	SPREADS	SECTIONS
Cellularity	Varies with technic	Consistent with true state of marrow
Relative distribution of cell species	Irregularities dependent on technic	Accurate reflection
Identification of individual cells	Better than in sections	More difficult than in spreads
Mitotic activity	Morphology of individual mitotic figures better than in sections	Quantitative aspect more readily apparent than in spreads
Histologic structure	Only implied	Readily discerned
Cytochemical studies	Material unsatisfactory	Material satisfactory
Lymphomata	Easily missed or not apparent	Readily identified
Granuloma lesions	Not seen	Readily identified
Maligancy	Individual cells or groups of cells irregularly distributed	Syncytial masses readily found; histologic arrangement may indicate source

Such appraisals are not based on spreads alone. Agress¹ has shown the value of studying sections (see page 943 for technic) and spreads simultaneously in order to obtain a true quantitative evaluation of bone marrow. A general comparison of the two methods is shown in Table 75 by Agress, which is based on his study of 1,187 cases in which bone marrow aspirations were performed.

¹Agress, H.: Comparative Study of Bone Marrow Spreads and Bone Marrow Sections, Exhibit at Clinic Session, A.M.A., Miami, Fla., 1954.

As can be readily noted from Table 75, many differences are apparent between spreads and sections. Perhaps the outstanding difference relates to quantitative appraisal.

It is not unusual to find spreads which appear extremely hypocellular, whereas the sections may appear quite normally cellular. On the other hand, individual cell morphology is more clearly studied in well-prepared spreads.

In this study, a correlation between spreads and sections of bone marrow was set up by Agress in relation to their being diagnostic. Table 76 represents this correlation.

There is close correlation between spreads and sections insofar as the over-all percentage in satisfactory preparations is concerned. However, in individual cases, the spread may be unsatisfactory and the section satisfactory. In other instances, the reverse may be true. This correlation is particularly important in the hypoplastic or aplastic states. Note that no cases of aplastic anemia were diagnosed on spreads alone and only 20 per cent were

diagnosed on sections of the clot obtained by routine marrow aspirations. The reason for this should be obvious. In those cases of aplastic anemia in which the bone marrow is almost completely replaced by fibrous tissue, routine marrow aspirations are generally doomed to failure. This diagnosis should not be made on the **absence** of cells from the spread **alone**. If sections of clot show no marrow units, the diagnosis still should not be made since the result may be purely technical in origin. In such an event, the marrow aspiration must be repeated or surgical trephine should be performed to get a truly representative specimen of bone marrow. This figure also gives some suggestion of what the physician might expect diagnostically from bone marrow aspiration.

Like all other laboratory examinations, marrow studies have their limitations and serve their most useful purpose only when correlated with the clinical aspects of the patient. Bone marrow aspiration should not be performed prior to a thorough history, physical examination, and at least routine laboratory studies. This is particularly true in the vast majority of anemias, except pernicious anemia and a few others. In relation to pernicious anemia and related macrocytic anemias, it is important to remember that erythrocyte maturation factor in even modest dosages will convert the bone marrow pic-

ture considerably. For this reason, folic acid, liver, and vitamin B₁₂ should not be administered prior to marrow aspiration. Table 77 by Agress is an outline of the indications for marrow aspirations. The cases listed under "hypersplenism"¹ are particularly to be stressed since this is the group in which splenectomy may exert a very favorable influence.¹ It is well to remember that selected cases displaying the features of hypersplenism may be primarily due to metastatic carcinoma of the bone marrow. Splenectomy could serve no useful purpose in such cases. For this reason, bone marrow aspiration should be performed in all cases in which splenectomy is contemplated as a form of treatment for a blood dyscrasia. It has been our experience generally that the best results in this group of cases come in those patients whose bone marrow contains a normally active or hyperactive picture of the blood element or elements affected. For example, we do not recommend splenectomy in a case of idiopathic thrombocytopenic purpura unless the bone marrow shows a fairly good representation of megakaryocytes. Using this criterion alone our

results with splenectomy have been exceedingly favorable. Much has been written about the bone marrow picture in idiopathic thrombocytopenic purpura as related to splenectomy, and there is no evidence other than the presence of adequate numbers of megakaryocytes (mature or immature) upon which the many observers will agree.

The second group of cases with a bizarre blood picture forms a rare heterogeneous group that covers the horizon of medicine. It includes individual cases of drug intoxications, familial cell defects, or the unusual reflection of some well-known disease. It may include leukopenias or hyperleukocytosis as well as unusual cells in the peripheral blood. Abnormal forms of erythrocytes as well as unexplained anemias should be included here. Thrombocytopenias or morphologically abnormal platelets ("giant platelets") are included in this group. Many of these cases are associated with organ enlargements, such as the spleen and liver, suggesting some blood dyscrasias. Some

of these cases are examples of "hypersplenism," and as our knowledge of immunohematology broadens, they are being more accurately categorized. Some of these cases are in reality malignancies with or without demonstrable bone marrow metastases.

The diagnosis of bone marrow invasion by metastatic carcinoma is dependent upon a number of factors, most important of which is a high index of suspicion. In our experience, the finding of *one or more normoblasts in the*

peripheral blood of an adult not having an obvious disease explaining the presence of normoblasts is one of the most important indicators of possible malignant invasion of the bone marrow. Not all cases of bone marrow malignancy

show normoblasts in the peripheral blood, but when normoblasts are present, we pursue the possibility of malignancy vigorously. We have uncovered two cases of unexpected malignancy with normal blood values, in which normoblasts were found on routine blood spreads. The success with which marrow

aspiration will reveal metastases is dependent upon the vigor with which such searches are made. If multiple sites are aspirated and numerous slides examined, the positive results may be very high. Sections of bone marrow clot often will show tumor cells otherwise difficult to find in spreads alone. The section technic outlined by Agress (page 943) may also give some information as to the original site of the malignancy by the histologic structure assumed by the tumor cells.

Bone Marrow Findings in Multiple Myeloma

Multiple myeloma is a form of malignant tumor occurring in the skeletal trunk of adults and infiltrating the marrow cavity of numerous bones. It has been found in people within the age group of 30 to 75 years, the greatest incidence being at the age of 35 years. It affects the ribs and spine and the upper ends of the long bones, but the flat bones of the skull and pelvis may also be implicated. Ewing¹ states that myeloma means a tumor of the specific bone marrow cells, this including lymphocytes, granular leukocytes, and the red cell series, but excluding tumors arising from fatty tissues, blood vessels, and those derived from indifferent endothelial cells. There are four types of myeloma: the plasma cell type, the myelocytoma, the lymphocytoma and the erythrocytoma. Geschickter and Copeland² gave six cardinal signs, two or more of which they thought were constantly present. These were: "(1) Multiple involvement of the skeletal trunk in an adult; (2) pathologic fracture of rib; (3) excretion of Bence-Jones bodies*; (4) characteristic backache with signs of early paraplegia; (5) an otherwise inexplicable anemia; and (6) chronic nephritis with high nitrogen retention, low blood pressure, and high serum proteins." Cases have been reported with none of these signs present. Beizer, Hall, and Giffin³ point to other characteristic signs of this disease, which are: (1) Hyperproteinemia, with reversal of the albumin-globulin ratio; (2) hypercalcemia with normal or high serum phosphorus; (3) evidence of autohemagglutination in the counting chamber, on blood films, or detected by the cayenne pepper appearance of blood in the small vessels of the fundus when viewed through the ophthalmoscope while pressure is being placed on the eyeball; and (4) the appearance of an anticomplementary reaction when a complement-fixation test is being carried out. That none of these signs is pathognomonic is obvious.

Mistakes are easy when dealing with a supposed case of multiple myeloma. These cases may be mistaken for metastatic skeletal lesions, hyperparathyroidism, spondylitis, nephritis, and leukopenic leukemia, or vice versa. Quite frequently the suggestion of the existence of this disease comes from a suspicious x-ray picture.

Confirmation may be made by sternal puncture. Rosenthal and Vogel⁴ state, "A definite diagnosis of multiple myeloma is possible during life only when made by means of sternal biopsy or the more simple aspiration method of Arinkin." Beizer et al.⁵ studied ten cases. In four cases backache was the

principal symptom. In one case, cervical pain was present and in another case arthralgia. Three cases sought relief of an existing anemia. In seven of the ten cases, x-ray pictures suggested the diagnosis.

A modified Arinkin method was used by these workers. From one to one and one-half cubic centimeters were aspirated from the sternal marrow into a paraffin-lined test tube containing a small amount of heparin. Spreads were stained by Wright followed by Giemsa stain. Diagnosis is confirmed by finding typical myeloma cells. An increase in the typical and atypical plasma cells is also suggestive of multiple myeloma. However, these investigators very properly caution that an absence of these findings in sternal marrow does not rule out the diagnosis.

Myeloma cells show an abundant, definitely outlined and deeply basophilic cytoplasm, a moderately sized round, excentrically placed nucleus having a fairly coarse chromatin sharply demarcated from the parachromatin, and a very large nucleolus.

Beizer calls attention to the fact that minor variations from this description may exist. The amount of cytoplasm varies from a narrow rim about the nucleus to a large quantity in others. Multiple small vacuoles may occur. A perinuclear zone may be seen. In one case they found 27.5 per cent plasma cells. These plasma cells had an excentrically placed nucleus containing coarse clumps of chromatin, and a few cells with somewhat larger nuclei, but no nucleoli, were seen. They emphasized the fact that the myeloma cell shows a large nucleolus and that in examinations of over 160 bone marrows no such cell was ever found in connection with any other pathologic process. Our own experiences convince us of the accuracy of Beizer's observations as to the specificity of the myeloma cells and also as to the occurrence of many plasma cells in this condition (see Plate XXVII).

Bayrd and Heck¹ mentioned that a negative diagnosis resulting from sternal aspiration is not always adequate evidence for excluding the possibility of multiple myeloma. Changes in the bone marrow may be irregularly distributed rather than diffuse, and the results on repeated aspirations are not uniform. In one instance in their experience a third aspiration of marrow was necessary to secure a diagnostic specimen.

So far as myeloma cells or atypical plasma cells are concerned, Osgood and Hunter² found 45 to 54 per cent of plasma cells in one case of a 49-year-old man. Osgood and Hunter considered this to be a true instance of plasma cell leukemia and not multiple myeloma with myeloma cells in the peripheral blood. They held splenomegaly, epistaxis, bleeding from the gums, and the clinical course which this patient pursued to be of the type characteristic of leukemia. As further evidence they cited the lack of Bence-Jones proteinuria, of "typical" defects of the bone in the roentgenograms, bone pain, and bone fragility. Others have felt that this is a distinction of degree only, not of kind. With this opinion Bayrd and Heck concur.

Meyer, Halpern, and Ogden³ reviewed all the known cases of multiple myeloma in which there were plasma cells in the peripheral blood and all the

¹Bayrd, E. D., and Heck, F. J.: *J. A. M. A.* 133: 3, 147-157, Jan. 18, 1947.

³Meyer, L. M., Halpern, J., and Ogden, F. N.: *Ann. Int. Med.* 22: 585-598, April, 1945.

purported cases of plasma cell leukemia, of which they listed four. In a careful consideration of these cases they expressed doubt that any were actually cases of true plasma cell leukemia. They rejected these cases largely on the ground that the absence of osseous lesions had not been adequately established. They did report one case which they considered to be a true case of acute plasma cell leukemia, although they considered it to "complete the chain in the analogy to lymphoid tumors" such as lymphoma and lymphocytic leukemia.

Diagnosis of Multiple Myeloma.—The various clinical and laboratory features of this disease are striking and the occurrence of multiple osteolytic lesions of the bone, Bence-Jones proteinuria, and hyperproteinemia is strongly suggestive evidence for the presence of multiple myeloma. However, as pointed out by Bayrd and Heck, every effort should be made to confirm this with pathologic material for the sake of accuracy of prognosis and suggestions as to an outline of treatment. To this end, because of its simplicity and broad diagnostic range, the method of sternal aspiration readily lends itself.

Diagnosis of multiple myeloma can often be made by bone marrow aspiration. In this disease, the normal bone marrow elements are replaced by large numbers of plasma cells. When the percentage of plasma cells is quite high (40 to 90 per cent), the diagnosis is relatively simple. However, there are many instances in which lower incidences of bone marrow plasmacytosis (up to 20 per cent) may leave some doubt as to the diagnosis. We have had an experience corroborating that of others¹ that an increase in plasma cells may occur in a large heterogeneous group of chronic diseases, such as pulmonary tuberculosis, malignancy (with or without marrow invasion), rheumatoid arthritis, syphilis, sarcoidosis, cirrhosis of the liver, gold intoxication, Banti's syndrome, bacterial endocarditis, periarteritis nodosum, myelofibrosis, chronic leukemias (especially when irradiated), and diseases either members of or simulating collagen disease. A rather interesting feature of many of these cases is that they display disturbances of blood protein relationships, often showing elevations of the globulin fraction. In none of these secondary plasmacytoses have we seen the very abnormal plasma cells found in most cases of multiple myeloma. These "myeloma cells," as they are referred to by some observers, are larger than normal plasma cells, ranging from 15 to 18 μ in diameter, and have a slightly pinkish cast to the cytoplasm. However, other cases of myeloma have plasma cells indistinguishable from normal plasma cells. In general, abnormal forms with two to six lobed nuclei are much more common in myeloma than in the reactive plasmacytoses, although we have occasionally found trilobed plasma cells in the latter. Mitoses may be quite common in myeloma and are often abnormal in configuration, as is frequently true in many malignant diseases. Sections of the bone marrow are helpful in isolated cases of multiple myeloma of the nodular type. In such instances, spreads might not show an increase in plasma cells but the sections may show solid nodules of myeloma cells. In other instances the marrow may be exceedingly fatty and the spreads give an impression of extreme hypoplasia with very few cells seen. The sections in such cases show the true character of the disease.

¹Klein, H., and Block, M.: *Blood* 8: 1034, 1953.

The Bone Marrow in Hodgkin's Disease

Hodgkin's disease has a fairly high incidence of marrow involvement in studies where extensive autopsy search has been performed. However, in routine bone marrow aspirations, the yield is disappointing. An increase of reticuloendothelial cells with an eosinophilia is suggestive. Rarely, sections of the marrow will reveal the typical Hodgkin's nodule. Out of 46 proved cases of Hodgkin's disease, in only 4 cases were Hodgkin's nodules found and in all these instances serial sections of the marrow clot were searched vigorously. As with other marrow lesions with a spotty distribution, the success in finding such lesions is dependent in great part on the multiple sites and the search of many sections.

The Bone Marrow in Leukemia

Leukemia in almost all forms can be readily diagnosed by study of the peripheral blood. The most common exception to this is the acute stem cell leukemia with a low white blood count. We have found such cases in all age groups from 2 to 84 years, but have seen it most frequently in the third and fourth decades of life. Organ enlargements, such as splenomegaly, hepatomegaly, and lymphadenopathy, are frequently absent or tend to be minimal. Anemia is usually quite obvious clinically and the erythrocyte counts are down to 1,500,000 or 2,000,000 red cells per cu. mm. with correspondingly low hemoglobin values. Hemorrhagic manifestations are a frequent accompaniment of the disease and reflect a striking thrombopenia. Leukocyte values have ranged from 400 to 2,000 per cu. mm. In all these cases we have been able to find leukemic cells in the peripheral blood, with varying effort required in individual instances. In some of these the leukemic cells have been only a small percentage of the cells in the peripheral blood. The diagnosis of leukemia could be made on peripheral blood studies alone. However, bone marrow aspiration readily corroborated our impression. In all these cases the marrow was exceedingly hypercellular with an almost complete replacement of normal marrow elements by the leukemic cells. The striking difference between the cellularity of the bone marrow and the peripheral leukopenia in this condition raises a basic question as to what factors determine the delivery of cells from the marrow to the circulation. One would certainly expect a tremendous leukocytosis in this condition. Perhaps peripheral destruction due to unknown immunohematologic factors plays a role in the leukopenia, anemia, and thrombopenia.

In the chronic leukemias, there is fairly good correspondence between the peripheral blood changes and the bone marrow picture. The marrow tends to be hyperplastic, with the increase in cells corresponding with the cell type in the peripheral blood. The degree of shift to younger forms is inclined to be more pronounced in the bone marrow than in the peripheral blood. It is not too unusual to see this disparity in chronic myelocytic leukemia, where only a few myeloblasts are present in the peripheral blood but the bone marrow may show many such cells. In chronic lymphocytic leukemia, approximately 85 per cent of our cases showed typical leukemic hyperplasia. In the other 15 per cent, lymphocytic increases were noted but the marrow was not completely replaced by abnormal lymphocytes. Cases of chronic lymphocytic

leukemia, which were effectively treated with x-ray therapy, often showed so few lymphocytes in the bone marrow as to make the diagnosis of leukemia impossible. This was only rarely true in chronic myelocytic leukemia where, even though the marrow became less hyperplastic, the "monstrosity forms" of leukemic development were qualitatively readily identifiable.

Monocytic leukemia, especially in the subleukemic and chronic forms, could usually be diagnosed by the presence of an increase in abnormal monocytes in the peripheral blood. However, our experience with such cases has been that it is not unusual to find only 12 to 25 per cent of such cells in the peripheral blood. When the increment of increase was in the lower ranges, there were occasions when some doubt was cast on the validity of the diagnosis of monocytic leukemia. In all these cases, the bone marrow showed a hyperplastic state due to an overabundance of abnormal monocytes.

The diagnosis of such rare entities as **erythroleukemia (di Guglielmo's disease)** cannot be made except with the aid of bone marrow aspiration. In the three cases which we have encountered, there was profound involvement of the erythrocytic series. In addition to hyperplasia of the bone marrow due to an increase in cells of this series, there were qualitative changes in the red cell development of extreme pathologic character. "Monstrosities" were numerous and consisted of abnormal sizes, shapes, and nuclear structures of the red cells. Some cells reached the giant proportions of 35 to 40 μ and had as many as 5 to 8 nuclei. There was marked asynchronism between cytoplasmic and nuclear development and mitotic figures were often abnormal.

The Bone Marrow in Pernicious Anemia

Bone marrow aspiration studies in the anemias are generally not very fruitful from a diagnostic standpoint. Perhaps they are of greatest assistance in the macrocytic anemias, with pernicious anemia the most outstanding example. In this condition the classical bone marrow picture can be seen under the following conditions: (1) a red blood cell count of 3,000,000 per cu. mm. or less, and (2) no erythrocyte maturation factor (liver, folic acid, or vitamin B₁₂) has been administered. When the red cell count is above 3,000,000 per cu. mm., the typical bone marrow picture rarely is present, and as the red cell count increases, there is less and less likelihood of finding a typical picture. We have encountered cases displaying the typical neurological syndrome of pernicious anemia with little or no anemia. Bone marrow aspirations in these cases have been of no help in diagnosis. Insofar as the effect of therapy is concerned, it is well to remember that even modest dosages of erythrocyte maturation factor will quickly alter the bone marrow picture so that within 24 to 48 hours after such therapy, it may be difficult to make a diagnosis of pernicious anemia. Whenever the diagnosis of pernicious anemia is even suspect, no liver or similar therapy should be administered before the marrow aspiration has been performed. Since such a diagnosis is so important in committing a patient to lifelong therapy, anything that interferes with an accurate diagnosis is to be avoided. Early diagnosis and adequate therapy are the only certain means of avoiding serious neurological complications. Suboptimal therapy may mask the hematologic picture while these neuro-

logical features stealthily impose themselves on the patient. Once they have firmly established themselves, even the most vigorous treatment may fail. These are but a few of the reasons for accurate diagnosis of pernicious anemia.

The bone marrow in pernicious anemia in relapse is markedly hyperplastic. When the marrow puncture is being performed, many cases display tenderness of the sternum. As the marrow material is removed, its hyperplastic character can be seen grossly. Spreads of the bone marrow readily reveal this hyperplasia, which is primarily erythrocytic. The myeloid:erythroid ratio is obviously altered, approaching a 1:1 ratio in most cases and even showing a 1:2 or 1:3 ratio in other instances. Erythropoiesis is of the "primitive" type, simulating that of the embryo in the prehepatic stage. There is a marked shift to younger forms with the megaloblast the stem cell from which the red cells originate. Not only is there seen a profusion of megaloblasts but there is also noted a marked increase in other young forms, such as basophilic normoblasts and polychromatophilic normoblasts. Pathologic erythropoiesis reaches its greatest proportions in the bone marrow in pernicious anemia, being approached only in the rare cases of di Guglielmo's disease or other leukemic disease. These pathologic changes affect the cytoplasm as well as the nuclei of the red cells and consist of the following changes:

(1) Abnormal cell size. The megaloblast itself begins as a "giant" form, usually measuring 20 to 24 μ in diameter. There is little wonder, then, that the offspring of this cell are large. This developmental defect accounts for the macrocytosis.

(2) Asynchronism of development. In normal cell development, cell size, cytoplasmic staining, and nuclear size keep pace in an orderly manner. In pernicious anemia, this synchronism disappears. Large cells with small nuclei are common. Many cells may display an extremely basophilic cytoplasm and have the nuclei of fully developed normoblasts.

(3) Karyorrhexis of nuclei. Fragmentation of nuclei at all stages of development is readily apparent. This may vary from simple binucleated cells to erythrocytes containing one large nucleus surrounded by single or multiple Howell-Jolly bodies. Other red cells may display Howell-Jolly bodies only.

(4) Karyolysis of nuclei. Whereas normal nucleated red cells show karyolysis of the nuclei by a diminution in size, the erythrocytes of pernicious anemia frequently display this phenomenon within the nucleus. As a result, the stained nucleus takes on a "soil erosion" appearance, showing alternating areas of well-stained chromatin alongside areas which do not stain at all or stain a reddish hue. Not only can this phenomenon be seen in sizeable nuclei, but it is often visible in Howell-Jolly bodies as well.

(5) Mitotic activity is exceedingly great and is abnormal. The abnormalities take on many bizarre features. It is not unusual to see one or two chromosomes off by themselves in one part of a cell away from the major mitotic figure. When the mitotic figure shows separation of the chromatin, one pole may show considerably more material than the other. Abnormal condensations of chromatin are often noted and lysis of the chromatin in mitotic figures (just as in the intact nuclei) is observable.

There is a feature of pernicious anemia bone marrow that is mentioned fairly frequently but is rarely stressed, even in hematology texts, and this relates to the abnormal leukocyte development in this disease. This pathologic myelopoiesis is as regularly occurring in pernicious anemia as are the red cell changes; and it disappears with specific therapy just as promptly as the abnormal erythropoiesis. The most striking abnormality is the finding of "giant" white cells, particularly notable at the promyelocyte, myelocyte, and juvenile stages, reaching a size of 20 to 22 μ in diameter. In many of these cells there often is an inordinately great amount of nuclear material, giving the impression that the cell has all that it can do to contain the nucleus. When such cells go on to full maturity, they typify the "pernicious anemia neutrophile" with its increased size and multilobulated nucleus. Mitoses in the myelocytic series are increased and occasionally are abnormal.

The only other macrocytic anemias that we have encountered which are indistinguishable from pernicious anemia have been observed in tropical and nontropical sprue and in a rare case of *Diphyllobothrium latum* infestation. In all other instances, the differential diagnosis has been relatively simple. Advanced liver disease, such as cirrhosis, is occasionally associated with a macrocytic anemia. In none of the cases we have studied have we seen the degree of pathologic erythropoiesis and myelopoiesis observed in pernicious anemia in relapse. Macrocytosis may be striking in such cases but the other pathologic features are lacking. This has been true in cases of carcinoma (especially of the stomach), pernicious-like anemia of pregnancy, and some refractory anemias.

The Bone Marrow in Anemias

Insofar as anemias, other than the macrocytic group, are concerned, bone marrow aspiration is rarely diagnostic. The anemias of chronic hemorrhage and of hemolytic disease often show a nonspecific normoblastic hyperplasia of varying degree. This can be demonstrated in both spreads and sections of marrow. Aspirations of bone marrow in these cases is at times helpful in eliminating other diagnoses but the positive aids in anemia of this group come chiefly from history, physical examination, and peripheral blood studies.

There is a group of anemias in which **sections** of bone marrow material have given us more information than do the **spreads** of the same material. These include the anemias associated with malnutrition, terminal nephritis, and advanced liver disease. In all these instances, the sections of marrow show a marked increase in fatty marrow which replaces normal marrow. The marrow hypoplasia may become so marked that only isolated islands of blood-forming tissue can be seen interspersed between large fat globules.

The Bone Marrow in Polycythemia

In polycythemia, whether secondary or primary, there is a hyperplasia of all marrow elements which can be quantitatively appraised better in sections than in spreads. Block and associates¹ have used the appearance of sections as a guide for therapy in polycythemia vera. If the marrow sections show marked hyperplasia, they recommend further active radiation therapy,

¹Block, M., Bethard, W., and Jacobson, L. O.: Proc. Central Soc. Clin. Invest. 27: 17, 1954.

regardless of the peripheral blood values. We have noted an interesting and undescribed phenomenon in polycythemia vera related to the megakaryocytes. These cells show an unusual degree of cytolysis with all the cytoplasm of almost every megakaryocyte showing platelet formation and leaving bare nuclei surrounded by platelets. This phenomenon might account for the thrombocytosis commonly associated with polycythemia vera and has not been observed in the secondary polycythemias.

The Bone Marrow in Malignant Lymphomata

Malignant lymphomata at times may be diagnosed by bone marrow aspiration. For this diagnosis we still prefer biopsy of lymph nodes over bone marrow aspiration because the former will yield a higher return than the latter. Table 76 requires a word of explanation. The 100 per cent diagnosis under sections as compared with only 9.4 per cent positives in spreads are comparative figures between the two technics. We have not found that 100 per cent of lymphosarcomata can be diagnosed by marrow aspiration but that when the diagnosis is made this way, the sections of marrow will show it ten times as frequently as the spreads. This disparity between the two technics is readily comprehensible when one observes numerous sections of such cases.

Lymphosarcoma has a tendency to form **nodules** in bone marrow rather than to be diffusely spread throughout the marrow. The usual picture is that of a central nodule, consisting solely of lymphosarcoma cells, within a marrow unit, the periphery of which consists of normal marrow elements. Not infrequently this peripheral zone shows a marked eosinophilia. Alongside such affected marrow units may be seen perfectly normal units and these generally outnumber the involved areas. In the preparation of spreads from such material, if one does not happen to catch a nodule of lymphosarcoma cells, the diagnosis will be missed. We have the impression that these lymphoid nodules are held together rather compactly and do not spread well. In the spreads in many of these cases, one may encounter a moderate increase in abnormal lymphocytes but only of sufficient degree to arouse suspicion of the diagnosis. A generalization that appears reasonable from our observations is that when there is an increase in abnormal lymphocytes in the peripheral blood, the bone marrow is likely to show a diffuse spread of these cells. This is the pattern of chronic and acute lymphocytic leukemia and of leukosarcoma. As a corollary to this observation, when we see the nodular type of lesion in the bone marrow, then abnormal lymphocytes are rarely seen in the peripheral blood. At times, we have observed one type transform into the other, most frequently the nodular type changing into the diffuse type of disease.

A word of caution is in order concerning lymphocytic nodules in bone marrow. Isolated nodules may be seen in normal bone marrows and in our experience are fairly regularly encountered in elderly subjects, particularly those with malnutrition. The finding of an isolated lymphocytic nodule, therefore, does not make a diagnosis of lymphosarcoma. We insist on the finding of goodly numbers of such nodules before making this diagnosis. In well-prepared thin sections, it is often possible to identify individual lymphocytes which are abnormal. An increased incidence of mitoses adds further weight to the diagnosis.

We have found bone marrow aspirations helpful in two situations where lymphosarcoma is suspect. By far the largest group has been those patients who have mediastinal or abdominal involvement and no readily accessible peripheral lymphadenopathy. Marrow aspiration in these cases is a much simpler approach to diagnosis than thoracotomy or abdominal exploration. The other situation in which we have found marrow aspiration useful is in determining the extent of involvement of the disease. We have observed patients with lymphosarcoma of the skin, with no significant organ enlargements or lymphadenopathy, who have shown extensive marrow involvement. In these cases we have recommended more vigorous therapy than would have been used for the skin lesions themselves. Prognostically, the cases with marrow involvement have had a poorer outlook than those without such spread of the disease.

Infections and Bone Marrow

The usual response of the bone marrow in acute infection is a moderate hyperplasia of the myelocytic elements with a left shift in this series paralleling the shift seen in the peripheral blood. At times this shift may reach the proportions seen in chronic myelocytic leukemia. These are several helpful differential points in the bone marrows of these two conditions, as listed in Table 78.

TABLE 78

	INFECTION	MYELOCYTIC LEUKEMIA
Toxic changes in leukocytes	Present	Absent
"Monstrosity" forms	Absent	Present
Increased basophiles	Absent	Often present
"Hiatus" phenomenon	Absent	Often present
Myeloblasts	Few	Usually plentiful

In the field of chronic infections with specific granuloma lesions, bone marrow studies may make the diagnosis. Brucellosis, tuberculosis, and histoplasmosis are examples of this group. The success in finding these lesions is dependent on the multiplicity of punctures and the vigor with which the search for them is conducted. Obviously, sections of the bone marrow are superior to spreads. Granuloma lesions, such as sarcoid, belong to the same category.

Spreads may be helpful in finding the organisms of leishmaniasis, histoplasmosis, and toxoplasmosis. Although articles have appeared suggesting bone marrow studies for malarial infestations, we have not found this procedure necessary. After an extensive experience with malaria in the Armed Forces, our recommendation in this search for malaria is thorough knowledge of the thick drop technic. We were not able to find a single instance of malaria in which we could demonstrate the parasites in bone marrow material and not find them as readily in thick drop preparations.

Culture of bone marrow for isolation of certain organisms has been successful in isolated instances, such as brucellosis and tuberculosis.

The Bone Marrow in Aplastic Anemia and Myelofibrosis

In these states the bone marrow may become exceedingly hypocellular or almost completely replaced by fibrous connective tissue. Some comment has already been made concerning the relative merits of spreads and sections in these conditions, with the section technic holding the upper hand. If, however, successive "dry" taps are encountered, surgical trephine should be performed before making such a diagnosis.

In addition to the above-mentioned idiopathic state, we have encountered variable degrees of marrow fibrosis in other conditions. The chronic blood dyscrasias, such as leukemia and polycythemia, which have received significant amounts of radiation therapy may show a considerable degree of fibrosis. The same is true of Hodgkin's disease treated with radiation or nitrogen mustards. Some cases of metastatic carcinoma show extensive fibrous replacement of bone marrow. We have observed this to be particularly true in cases where we were able to demonstrate capillaries plugged with tumor cells. In most of our cases of metastatic carcinoma, this was not true; normal marrow units were seen alongside large aggregates of tumor cells. A few cases of sarcoidosis and a rare case of widespread tuberculosis showed marked replacement of normal marrow.

Contraindications to Marrow Aspiration

Bone marrow aspiration is not indicated until adequately complete history, physical examination, and peripheral blood studies have been performed and indicate the desirability of the procedure. In addition to the discomfort to the patient, the procedure carries some danger, a few deaths having been reported as a result of bone marrow aspirations. Perhaps the only medical contraindication to marrow aspiration is hemophilia, in which uncontrollable bleeding may follow the puncture.

The Technic of Bone Marrow Investigations

The first instrument for the examination of bone marrow was made by Wolff¹ in 1903. This examination was performed by trephination of the diaphyses of the tibias of small animals. Human bone marrow of a living subject was first examined by Ghedini² in 1908. This method, following the method of Seyfarth, was used by Schilling and this author (R. B. H. G.) for some time, but has been superseded by the relatively simple process of direct sternal puncture instead of trephining as we previously performed this technic. The difficulties incident to an operation of the type of trephination were removed by Arinkin³ in 1929. He used a large needle and trocar and punctured the body of the sternum under aseptic conditions, using a local anesthetic.

Gradwohl⁴ reported a new instrumentarium for performing sternal puncture. It consists of a 10 c.c. Luer Lok syringe, a cannula and connector with a rubber tubing joint, a bone marrow puncturing instrument with a guard which can be adjusted to fit the depth of the sternal puncture, and an obturator for the latter.

¹Wolff, A.: *Deutsche med. Wchnschr.* 29: 165, 1903.

²Ghedini: *Wien. klin. Wchnschr.* 23: 1840, 1910.

³Arinkin: *Folin haemat.* 38: 233 (June), 1929.

⁴Gradwohl, R. B. H.: *J. A. M. A.* 108: 803, 1937.

The skin over the sternomanubrial junction is surgically prepared, the usual sterile drapes are applied, and local anesthesia with procaine hydrochloride solution is injected intradermally, subcutaneously, and into the periosteum. The instrument for puncture has a handle which permits a firm grasp and allows one to bore through the external lamina of the sternum and enter rapidly the marrow cavity of this bone. The instrument is thrust through the skin at the sternomanubrial junction at right angles to the surface of the sternum. The guard on the shaft of the needle is so adjusted that the instrument

Fig. 220.—The Gradwohl-Aloe sternal marrow puncture apparatus: *A*, syringe; *B*, cannula and connecting tubing; *C*, bone marrow puncture instrument; *D*, obturator.

Fig. 221.—Bone marrow touch preparation.

cannot possibly be pushed through the sternum into the mediastinal space. After the instrument has well penetrated the sternum, the direction is changed with the point directed upward. At this time, when the marrow has been entered, the obturator is removed, the connector and syringe are attached above the handle of the boring instrument, and suction is applied. One obtains in this way a very definite specimen of the bone marrow. It goes without saying, of course, that the entire instrumentarium must be adequately sterilized before use. One may place a small amount of dilute sterile sodium citrate solution in the barrel of the syringe, which slightly dilutes the bone marrow material.

The large caliber of the instrument permits one easily to obtain sufficient bone marrow. Once the marrow is obtained, the instrument is rapidly removed and the opening closed with a surgical dressing. Repeated punctures on the same patient can be made with this instrument without any difficulty.

It is not necessary to remove a large quantity of bone marrow. Only a small amount is obtained, usually about 0.2 to 0.3 c.c.

Fig. 220 shows the entire set-up for the procedure.

Turkel Technic for Biopsies of Sternum

The Turkel trephine biopsy method eliminates the two common objections to marrow biopsies—(1) that biopsy is a surgical procedure, and (2) that biopsy leaves a disfiguring scar.

The advantages of this method are that it is easily and rapidly performed at bedside or office and does not leave a disfiguring scar. It controls the depth and force of penetration; in other words, it prevents penetration of posterior lamella and mediastinum. There is no dilution of marrow with circulating blood. There is preservation of marrow topography. The biopsy by this method shows cells adherent to the marrow wall which are not seen by aspiration. Further, the biopsy shows the true proportion of cells in marrow, or the myeloid-erythroblast ratio. It checks results of treatments quantitatively. It possesses the advantage that aspiration and infusion may be performed through the same aperture.

Fig. 222.—The Turkel needle for aspiration or biopsy of the sternum.

Technic.—

Cleanse the skin over the desired site, usually opposite the third rib, with surgical antiseptic. Infiltrate skin, subcutaneous tissue, and periosteum with local anesthetic.

Insert outer needle with styler in place (Fig. 222) with the tip of the needle in the direction of the face of the patient at an angle of about 45 degrees, through the skin, subcutaneous tissue, and periosteum, until the tip just engages the anterior lamella of the sternum.

Leave the outer needle in place and remove the styler.

Insert the trephine needle with styler into the outer needle.

Remove styler of inner trephine needle.

While holding the outer needle with the fingers of the left hand, turn the head of the trephine needle with the fingers of the right hand, with a slight clockwise-counterclockwise motion, at the same time exerting gentle inward pressure. A sudden release of resistance signifies entrance of the trephine tip into the sternal cavity. The clockwise-counterclockwise

motion, with slight pressure, should continue until the neck of the inner needle is completely within the head of the outer needle. Rotate the head of the inner needle in order to detach the plug from the surrounding marrow.

(a) **For Aspiration.**—While holding the knurled handle of the inner needle, push the outer needle into the sternum about 6 mm., until the neck of the inner needle becomes completely visible. Remove the inner needle. Attach the syringe, aspirate about 1 c.c. of blood-marrow mixture. Remove syringe, express mixture immediately into oxalated tube.

(b) **For Biopsy.**—Remove the inner needle and with its stylet force the marrow plug into a bottle containing a fixative or use it as imprint or spread.

Insert stylet into outer needle, remove outer needle, and cover the point of insertion with antiseptic dressing.

Marrow Biopsy, Tibia

In infants and younger children it is safer to utilize the tibia instead of the sternum in obtaining bone marrow specimens. Except for the location, the technique is the same as that used in sternal puncture.

Use of Iliac Crest in Bone Marrow Punctures*

Bone marrow can be obtained easily and safely from the iliac crest and may at times provide information not obtainable from sternal aspiration.

Technic.—

The site for the iliac crest puncture is chosen on the crest over an area within 3 cm. posterior to the anterior superior iliac spine on either side of the body. According to the thickness of the tegument a needle 1 inch to 2½ inches long, 16 gauge, and furnished with a stylet, is used for puncture; a 20 cm. tightly fitted dry syringe is used for aspiration.

The determined site is prepared with iodine and alcohol and infiltrated with 2 per cent Novocain solution until the periosteum is reached; the periosteal space is then injected very slowly; usually no more than 2 c.c. of the Novocain solution are required. The patient lies in the supine position; in cases of very pronounced abdominal distention (ascites, enlarged viscera) the patient is tilted on his side. The puncture is performed with the needle held at a 45 degree angle to the long axis of the body and with pressure applied by the palm of the hand. The aspirating needle is forced into the bone with steady pressure and slight rotation. A distinct "give" sensation is usually felt when the needle enters the medullary cavity. As the needle is firmly embedded in the medullary cavity the stylet is withdrawn and the syringe attached to the needle. In order to avoid admixture of blood the plunger is slowly withdrawn until the first drop of marrow fluid is observed in the capillary end of the syringe. Bone marrow aspiration is accompanied by a slight sensation of pain (suction pain).

The material removed may be used in the usual way for enumeration of total nucleated cell count, for preparation of smears, and for section study.

The technical advantages of iliac crest versus sternal puncture are:

1. No injury can be sustained by any underlying organ.
2. Usually the iliac puncture is a less painful procedure and the patient is less apprehensive than when subjected to the puncture in the cardiac area.

*Michael A. Rubinstein, Montefiore Hospital, New York, N. Y. Personal communication based upon facts by Dr. Rubinstein in his Scientific Exhibit, A. M. A. convention, Atlantic City, N. J., June, 1947.

3. Repeated aspirations of the iliac crest can be easily performed at frequent intervals on both sides; iliac aspiration is very suitable for serial bone marrow studies. This may be important especially in experimental pharmacologic physiologic research of hematologic tissue and bone marrow tumors.

It is suggested that the marrow cavities of the iliac bone can be used as a readily available route of administering fluids into the general circulation when no intravenous route is accessible and they allow for greater safety than the sternal technic.

Disadvantage of the iliac aspiration is the occasional difficulty of puncturing the bone which at times may prove to be exceedingly firm in this region.

Bone marrow studies were performed simultaneously in iliac crest and sternal aspiration in 216 different cases showing normal and pathological findings.

Normal Values.—The normal values of the iliac bone marrow were found to be approximately in the same range as those determined for sternal aspiration. Iliac crest counts in hematologically active bone marrow in all age groups of normal individuals studied (age range 16 to 78 years) gave the following results: The total nucleated cell count of the iliac bone marrow, as that of sternal aspiration, tends to decrease with age from the average of 110,000 per cu. mm. in persons under twenty to 50,000 per cu. mm. in those over sixty. The differential count of the normal iliac marrow ranged as follows: myeloblasts, 0.5 to 2%; promyelocytes, 1 to 5%; myelocytes, neutrophilic, 11 to 23%; myelocytes, eosinophilic, 1 to 3%; myelocytes, basophilic, 0.5 to 1%; nonsegmented neutrophiles, 8 to 29%; segmented neutrophiles, 5 to 15%; eosinophiles, 1 to 3%; basophiles, 0.5 to 2%; lymphocytes, 2 to 10%; plasma cells, 0.5 to 3%; reticulum cells, 0.5 to 2%; hematogones, 0 to 3%; proerythroblasts, 0.5 to 1%; erythroblasts, 2 to 8%; normoblasts, 10 to 21%. The number of megakaryocytes ranged between 22 and 88 in 1 c.mm.

Examination of Bone Marrow Preparations

Touch preparations are made on the surfaces of clean, fat-free glass slides. A few spreads also are made. See method of Agress, page 943.

The combination of Wright and Giemsa stain is the best staining method. The specimens are dried in the air and stained with Wright stain 1 minute followed by differentiation in neutral distilled water for 5 minutes and then washed. (Carry out the usual Wright staining procedure, page 620.) The specimens are then stained for 30 minutes with a dilute Giemsa stain made by adding a drop of stock Giemsa stain to each c.c. of neutral distilled water.

After the staining process is completed the slide is washed with neutral distilled water, dried in the air, and examined. This combination stain gives excellent results.

In connection with the technic of bone marrow investigations, which is described above, a communication by Isaacs¹ outlines his method of counting the cells of the bone marrow which is of inestimable benefit in the determination of the type of anemia. The description is as follows:

Wet the inside of the tube of a Sahli hemoglobin pipette, or the stem of a red or white blood cell counting pipette with serum. The pipette stem should have markings enabling one to measure 4 volumes. A serum of the same blood group as the patient is desirable if the red blood cell count is a factor, otherwise any blood serum may be used. The serum is drained out, and bone marrow is sucked up 1 unit of space into the pipette. By working the tip back and forth among the trabeculae of bone, enough marrow may be obtained without air bubbles. Serum is then drawn up so that the total bulk is 4 volumes. This is then discharged into a watch glass, using care to wash out all of the marrow. Eight more volumes of serum (measured by the markings on the pipette) are then added, and the suspension is stirred thoroughly with a blunt glass rod. This suspension is then drawn into a red blood cell counting pipette to the 0.5 mark, and diluted with Hayem's solution, or with 1% acetic acid if a count of leukocytes only is desired, the rest of the steps being exactly as in the case of counting red blood cells, using a hemacytometer slide. The high-dry objective is used. The

¹Isaacs, Raphael: *Am. J. M. Sc.* 193: 181-191, February, 1937.

total number of cells in 4 or 8 sq. mm. are counted, the adult red blood cells being enumerated in one group (if acetic acid has not been used) so that when their number is subtracted from the total, the number of nucleated cells of all types is obtained. The calculations are as follows:

The number of cells counted in 1 sq. mm., obtained by dividing the total number of cells counted by the number of square millimeter spaces used, is multiplied by 24,000; i.e.,

$$\frac{10 \times 12 \times 200}{\text{No. of sq. mm.}}$$

The differential count is made from cover glass films, using a thick emulsion of bone marrow in serum. The fresher the serum, the better are the results. If the serum is of the same blood group, the red blood cells show a better distribution than when they are agglutinated. Human serum may be used for bone marrow of animals. Use Wright or Giemsa stain. When Wright stain is used, allow the stain to act for 1 minute, then dilute with as much distilled water as the cover glass will hold, mixing very thoroughly. Allow this to stand for 10 minutes, then wash with distilled water, dry and mount in xylol-balsam.

The most "representative" bone marrow is obtained from the midsternum, as this gives both red and white cells in the course of their development. This technic may be used with marrow from any bone or for cells of other organs.

With careful technic, the variation in counting cells from the same region in the normal marrow, using several pipettes, averages about 5%, an amount but slightly greater than variations from drop to drop in the same pipette. In pathologic marrows, where there was a grossly uneven distribution of the cells, the variation was considerably greater, amounting to as much as 24% between a cellular and relatively noncellular region, and to 85% in marrows with regions of "aplasia."

With this method, Isaacs maintains that there are from 150,000 to 300,000 cells per cu. mm. in normal sternal bone marrow. He states that the "primitive blast" stage of the cells of the polymorphonuclear leukocyte series resembles that of the lymphocyte and erythrocyte series of cells in general morphology, and may or may not be identical. The next stage in the development of the red blood cell he terms the megaloblast, and believes that this is a normal stage in the production of the erythrocyte rather than a pathologic or fetal cell, as many other authorities believe. He calls the next stage in development the basophilic normoblast or macronormoblast. Isaacs calls attention to the variation in the number of cells in the bone marrow dependent upon changes in physiology. In other words, a normal individual may tax his granulopoietic tissue at one time more than another in trying to remain normal. His view of the normal composition of the cells of bone marrow follows:

	PER CENT OF ALL NUCLEATED CELLS
Undifferentiated "lymphoid" cells. "Primitive blasts" -----	23.1 ± 8.0
Megaloblasts -----	3.0 ± 1.0
Basophilic normoblasts -----	7.2 ± 2.5
Eosinophilic normoblasts -----	12.0 ± 7.0
Polymorphonuclear neutrophiles—adult -----	7.5 ± 5.5
Polymorphonuclear neutrophiles—young -----	13.0 ± 6.0
Metamyelocytes -----	20.8 ± 3.0
Myelocytes -----	2.8 ± 1.8
Myeloblasts -----	1.8 ± 0.8
Eosinophiles (immature and mature) -----	5.5 ± 3.0
Lymphocytes -----	1.0 ± 0.5
"Endothelial" cells. Phagocytes -----	0.9 ± 0.5
Hemohistioblasts and hemohistiocytes -----	2.3 ± 1.3
Megakaryocytes -----	0.5 ± 0.1
Basophiles -----	Present
Monocytes -----	Present

He calls attention to the fact that in aplastic anemia the total number of cells per cubic centimeter is greatly reduced and the fat content is increased. So-called idiopathic aplastic anemia differs from aplastic anemia following intensive roentgen ray therapy in that in the latter condition the number of primitive blasts is reduced, but the cells which are present tend to ripen into eosinophilic normoblasts and later into mature erythrocytes. In the hypoplastic anemia of nephritis the inhibition is just after the primitive blast stage, so that cells in this stage accumulate in normal or greater than normal numbers while but few ripen to the megaloblast stage.

In pernicious anemia, he found that the point of inhibition appears at the megaloblast stage. Inhibition appeared at the normoblast stage in leukemia and infection.

The next stages are eosinophilic normoblast, reticulocyte, polychromatic red blood cell, and the mature erythrocyte.

Agress Modification for Preparing Spreads and Sections Simultaneously

Perform marrow aspiration in the standard manner, using the site of the operator's choice or as indicated in individual problems.

Attach a *dry*, sterile, tight-fitting 5 or 10 c.c. syringe to the aspirating needle.

Make a *strong, sudden* pull with the plunger, withdrawing only about 0.5 to 1.0 c.c. of marrow. This first show of marrow generally is the most cellular and has the least dilution with blood.

Quickly transfer the entire contents of the syringe to a clean glass slide.

Touch this pool of marrow by the edges of successive slides and then spread over individual slides to make the spreads.

Generally 8 to 12 spreads should be made of each preparation.

Stain spreads as outlined on page 941.

When the pool of marrow has clotted, pick up the clot with the stylus of the aspirating needle, and transfer to a fixative. Thereafter treat like a routine surgical biopsy. Our preference in fixatives is Zenker's acetic acid (10%), which permits the use of special stains if desirable. The routine staining is hematoxylin and eosin, with particular care exercised in differentiation.

Using this method, Agress has found that 92 per cent of his spreads and 95 per cent of his sections are satisfactory.

Anticoagulants are *not used* at any time in the routine preparation of bone marrow spreads or sections. However, lupus erythematosus ("L.E.") cells will only rarely be found in using this technic. If L.E. cell preparations are desired, the method differs.

For L.E. Cells.—

Leave the aspirating needle in situ.

Aspirate 1 to 3 c.c. of marrow into a syringe containing a few drops of heparin or other anticoagulant.

Allow this material to incubate at 37° C. for 2 hours.

Centrifuge at 1,000 r.p.m. for 5 minutes.

Make spreads of the "buffy" coat, and stain in the routine manner. The method of staining is given on page 941.

For Cultures of Bone Marrow.—

If cultures of bone marrow are desirable, these, too, are collected after the routine method has been performed, leaving the aspirating needle in place. A clean, sterile syringe, containing sterile anticoagulant, is reapplied, and an effort is made to obtain as much as 5 c.c. of marrow material. This is then transferred to appropriate media.

Culture of Human Bone Marrow

Osgood has carried out some very interesting research work on cultivation of bone marrow. He has presented this work in various communications.¹ This method was used by him for the appraisal of therapeutic agents. It permitted determination of their effect on living human cells, of the toxic dose, and the minimum therapeutic dose, as well as the accurate control of concentration. He showed by his culture method a number of points about the length of life of neutrophiles, eosinophiles, and basophiles of normal blood by comparing blood and sternal marrow from healthy persons. The cultures were made in 30 c.c. vaccine vials in a medium consisting of about 35 per cent of human cord serum and 65 per cent of the balanced salt solution of the Geys.² This medium was previously determined by the Geys to be satisfactory for the culture of human tumors. Osgood found it possible to maintain cultures of human marrow in as nearly their natural state as any medium so far investigated. Note that the medium contains no substance not present in normal blood. The method by which he carried out this work is described by him in the *American Journal of the Medical Sciences*, February, 1938, vol. 195, pp. 141-144.

Method.—

Assemble the apparatus from 5 two-liter aspiratory bottles,* Pyrex standard wall glass tubing, and pressure tubing. Test its operation. Determine the volume of fluid in bottle 1 at the level of the inlet orifice of 4. Connections must be gas-tight under a pressure of at least 60 inches of water. Determine the number of drops per c.c. from tips 21 and 11. With water instead of medium flowing through the apparatus at the desired rate for use with the marrow, adjust the temperature of the water bath so that the temperature as determined on the fluid within 1 after a period of time for equilibrium to be reached is 37.5° C., the optimum temperature for the experiment. The temperature in the flask is usually about 1° lower than in the bath, but it should be determined for each experiment. Now disassemble the apparatus at convenient joints. Sterilize bottles 1, 5, and 9 with their connections as far as 23, in the autoclave, wrapping the free ends in paper or gauze. The gas system, including bottles 13 and 19 and their connections, need not be sterile. Reassemble the apparatus using aseptic technic, flaming the ends of glass tubes and pouring 70% alcohol on the rubber tubing before making each connection. Introduce the marrow, obtained as described by Osgood,³ into bottle 1 through vaccine cap 2.

Introduce medium³ with syringe and needle through rubber tube 7, previously sterilized with alcohol, into bottle 5. Close screw clamp 8. Force air in through 6 until the medium is all transferred to reservoir bottle. Used compressed air or a blood pressure manometer bulb. Disconnect bulb from 6 and adjust the flow of the medium from reservoir 9 by screw clamp 10, counting the number of drops per minute from tip 11, previously calibrated so that the c.c. per hour or 24 hours can be calculated. Any desired gas mixture can be made up in a spirometer and introduced into bottle 13 by closing screw clamps 14 and 15 and filling bottle 13 completely full with 5 to 10% sulphuric acid.⁴ Attach the outlet of the spirometer to inlet 16 and allow the gas to flow into bottle 13 by opening screw clamps 17 and 18, collecting the acid as it flows out in reservoir bottle 19, which is disconnected for this purpose.

*Any size container may be substituted for these without altering the principle of the method.

¹Osgood, E. E.: *J. A. M. A.* 109: 933-936, 1937. *Am. J. M. Sc.* 195: 141-144, 1938. *Am. J. Clin. Path.* 8: January, 1938.

²Gey, G. O., and Gey, M. K.: *Am. J. Cancer* 27: 45-76 (May), 1936.

³Osgood, E. E., and Brownlee, I. E.: *J. A. M. A.* 108: 1793, 1937.

⁴This prevents growth of molds and bacteria and dissolves less carbon dioxide than water.

When 13 is almost empty, close 18 and 17, place 19 back on its shelf, and attach to outlet 20. Open 14 and adjust the rate of flow of acid by the number of drops per minute of calibrated tip 21 to give the desired rate of gas flow. Open 15. Filter the gas leaving bottle 13 through sterile cotton 23, pass through trap 24; in passing down tube 3, it equilibrates with the medium flowing through the same tube as it enters culture bottle 1.

Fig. 223.—Osgood apparatus for bone marrow culture. (From Osgood: *Am. J. M. Sc.*, February, 1938.)

Medium¹ and gas enter through fine tip 3. The medium, being slightly cooler than that in the flask, flows across the bottom, and then gradually rises to the surface. Pressure of inflowing medium and gas forces the used medium and gas out through tube 4 into reservoir 5, from which the gas escapes through cotton-filled bulb 6. It may be collected if desired.

¹Osgood, E. E., and Brownlee, I. E.: *J. A. M. A.* 108: 1793, 1937.

If desired, tilt culture bottle 1 at any time so that the inlet of 4 is above the level of the liquid. Thoroughly mix by shaking, and aspirate marrow culture through 2 for counts and examination.¹ Calculate total numbers of any cell type present by multiplying the number per cubic millimeter by the volume of the culture in cubic millimeters. No semi-permeable membrane is necessary because the cells settle out and only the surface layer of fluid flows out through tube 4.

With this method, a rapid, controlled rate of flow of the medium past the cells and a rapid, controlled rate of gas supply is possible. Medium from bottles 1, 9, or 5 may be aspirated with a sterile syringe and needle through the pressure tubing at the outlet at any time for chemical, bacteriologic, or serologic examination. Medium may be used several times by pumping it as described from bottle 5 to bottle 9. Gas may be collected at 6 for analysis.

TABLE 79.—AZUROPHIL GRANULES

DIAMETER OF CELL IN RELATION TO LOBOCYTE	SIZE OF GRANULES	NUCLEOLI	CHROMATIN STRUCTURE	SHAPE OF NUCLEUS	PEROX-IDASE STAIN	NAME OF CELL
Same or smaller	Coarse	Present or absent	Coarse in clumps	Round or oval, sometimes irregular or cloverleaf	Negative	Lymphocyte
Larger	Coarse	Present or absent	Coarse	Round or oval, rarely irregular or cloverleaf	Negative	Prolymphocyte
				Round or oval, rarely horse-shoe	Positive	Progranulocyte A (Promyelocyte II)
			Very coarse	Round or oval	Negative	Plasmacyte†
			Fine	Round or oval, rarely horse-shoe*	Negative	Lymphoblast or granuloblast
	Fine, diffuse	Present	Fine	Round or oval Horseshoe or irregular	Negative Positive or negative	Monoblast Promonocyte
		Absent	Coarse clumps and strands	Horseshoe or irregular	Positive or negative	Monocyte
3 times as large	Fine, diffuse	Absent	Coarse clumps and strands	Horseshoe or irregular	Negative	Megalokaryocyte

*Rieder cell.

†Cytoplasm opaque. Plasma cells with azurophil granules are very rare.

He found that in cultures of human blood, by a technic which, with marrow, permits multiplication, maturation, and functional activity of cells of the granulocyte series for at least six weeks, the duration of life of the neutrophiles averaged sixty-one hours and, in the majority of instances, was between forty-eight and ninety hours. It seemed probable that these figures represented about the actual duration of life of these cells in the blood. The duration of the life of eosinophiles, from eight to twelve days, and basophiles, from twelve to fifteen days, determined by this method, is much longer than the duration of life of the neutrophiles.

In Table 79 from Osgood's article are collected the facts regarding the cells with azurophil granules. Table 80 from Osgood's article shows the facts relating to the cells with no granules.

¹Loc. cit. page 945.

Table 80 from Osgood's article shows the facts relating to the cells with no granules.

TABLE 80.—NO GRANULES (ALL HAVE ROUND OR OVAL NUCLEI)

CYTOPLASM	NUCLEOLI	CHROMATIN STRUCTURE	DIAMETER OF NUCLEUS IN RELATION TO DIAMETER OF CELL	SIZE OF CELL IN RELATION TO NEUTROPHIL LOBOCYTE	PEROXIDASE STAIN	NAME OF CELL
Opaque	Absent	Pycnotic	Less than half	Smaller	Negative	Metakaryocyte*† (Normoblast)
		Coarse	Less than two-thirds	Smaller	Negative	Karyocyte*† (Pronormoblast)
			More than two-thirds	Same or larger	Negative	Prokaryocyte* (Erythroblast)
		Coarse	Less than half	Usually larger	Negative	Plasmacyte†
	Present	Fine	Less than half	Usually larger	Negative	Proplasmacyte
			Less than two-thirds	Usually larger	Negative	Plasmablast
	Present	Fine	More than two-thirds	Same or larger	Negative	Karyoblast* (Megaloblast)
			More than half	Usually larger	Negative	Lymphoblast, monoblast, granuloblast (myeloblast)
Trans- parent	Present or absent	Coarse	More than half	Larger	Positive	Progranulocyte A (Promyelo- cyte II)
				Same or smaller	Negative	Prolymphocyte
					Negative	Lymphocyte

*May or may not contain hemoglobin. Other nucleated cells never contain hemoglobin.

†Sometimes two or more nuclei in one cell.

SPLENIC PUNCTURE¹

Splenic puncture requires withdrawal of splenic pulp without blood. Use oxidation-proof needle of steel or nickel, diameter 8 to 10 mm., and an absolutely air-tight syringe.

Produce superficial anesthesia by means of an intracutaneous Novocain wheal. Insert the needle into the superficial muscular plane, strictly in the zone of splenic dullness, immobilize the patient by asking him to hold his breath, give a short, but decided thrust, and rapidly and energetically aspirate, permitting the piston to return into its position of rest before the needle is withdrawn. Patient remains in bed for 12 to 24 hours. Ice is constantly applied to splenic region to prevent internal hemorrhage.

Splenograms are made by staining according to Wright-Giemsa (page 941), studying the aspect of the red cells and the relative number of hemato- blasts. The normal percentages are:

Neutrophilic polynuclears	20 to 30%
Eosinophilic polynuclears	1%
Basophilic polynuclears	Rare
Typical lymphocytes	50 to 60%
Medium mononuclears	10 to 20%
Monocytes	5 to 10%
Plasmacytes	1 to 2%
Normoblasts	20%
Naked nuclei	Numerous
Background, thick, sometimes granular	
Erythrocytes, normal	
Platelets, very numerous	

¹Perles, Suzanne: Paris méd. 25: 217-223, 1935.

The splenogram shows closer and more numerous cells than the corresponding hemogram. Abnormal erythrocytes are lacking. Platelets are present in larger numbers than in the peripheral blood. Determination of their number and coloration is one of the chief elements of splenic puncture.

Typical splenograms for each of the various pathologic reactions of the spleen are:

Lymphomatosis.—The splenogram of the lymphocytic leukemias is remarkable for homogeneity, achieved by the abundance of white elements, expressing the hyperplasia. Adult and young lymphocytes stand out from a clear and also homogeneous background. The young lymphocytes are much more numerous than in a normal splenogram (30 to 50, instead of 0.5 to 3 per cent), although the presence of all intermediary ages between a lymphoblast and a lymphocyte makes it difficult to make a clean differentiation. Polynuclear monocytes and plasmaocytes and especially normoblasts and megakaryoblasts are scarce, the latter even exceptional.

The uniformity and constancy of the splenic puncture observed in the lymphomatous diseases are a powerful argument for uniting forms apparently so far from each other as lymphocytic leukemias and pure splenic lymphomas.

Myelomatosis.—The splenogram of the myelomatoses is marked by a variegated aspect, which is due to the great changes of the elements of the myeloid series under the influence of age, and also to the more or less marked, but always noticeable, prevalence of a normomegakaryoblastic, exceptionally, megakaryocytic reaction. This notwithstanding, the myelomatous splenogram is a distinct and isolated type. The characteristic cells abound: myelocytes of all ages and all sizes, metamyelocytes, promyelocytes, primitive cells, hemohistioblasts, hemocytoblasts, polynuclears, and erythroblasts. The background is thick and granular, containing numerous platelets and poorly colored red globules.

Leukoblastoses.—The splenogram of acute leukemia shows a marked prevalence of the typical primitive cells (90 to 95 per cent). The other cells are more mature, yet decidedly young. These elements permit the tracing of the origin of the affection: lymphomatosis, myelomatosis, or erythroblastomatosis.

Cryptoleukemias.—A new chapter on leukemias, namely, one on atypical leukemias and cryptoleukemias (aleukemias or subleukemia) was written in terms of splenic puncture. These conditions were not capable of diagnosis by the ordinary methods of investigation. Whether or not the peripheral blood shows abnormal elements, the splenogram shows pullulation in the center of the atypical young cells.

SPLENIC TUMOR AND HEMATOLOGIC DIAGNOSIS

Enlargements of the spleen are very common. It is important to classify them, if possible, from clinical and hematologic standpoints. In blood diseases, the histologic structure of the splenic tumor is largely dependent upon which blood system is affected; for instance, the pulp, in cases of myelocytic leukemia, shows an increase in the myeloid elements; in lymphocytic leukemia, the lymphatic elements of the pulp increase; and in monocytic leukemia, there are many monocytes in the pulp. In polycythemia there is a marked hyper-

emia of the spleen and often a myeloid metaplasia. There is a disturbance in the spleen in purpura werlhofii, also in chronic leukemia, in aleukemia, and panmyelophthisis. It is interesting to note that benefit results in purpura werlhofii as well as in some cases of leukemia following splenectomy. In malignant tumors of the spleen, lymphocytes are found in the pulp, as in carcinoma, lymphatic sarcoma, etc. Single metastases in the spleen are rare. In benign megalo-splenia, due to reticular system disturbances, such as Gaucher's disease, Niemann's disease, etc., the spleen is filled with these substances such as cerasus phosphatin or cholesterolin. This can be determined by splenic puncture. The blood picture in these cases is not characteristic. In certain cases, there are anemia, leukopenia, and thrombocytopenia. There is a special form of splenic tumor seen in osteosclerosis. In these cases there is a chronic constitutional anemia.

In constitutional anemias, there are splenic disturbances by trauma, cirrhosis, postinfectious scars, etc. Banti's disease shows splenic tumor with anemia, later splenic and liver cirrhosis with ascites and cachexia.

In certain splenic tumor diseases, one notes increased urobilin and urobilinogen in the urine and chronic subicterus. Splenic tumors are due either to the breaking down of the poorly resistant erythrocytes as in icterus hemolyticus, or to deposited erythrocytes as in pernicious anemia or blood poisoning.

If the splenic function is markedly disturbed, one sees polychromasia, eosinophilia, with pathologic erythrocytic forms, an appearance of normoblasts, erythrocytes, inner bodies, etc. It is probable that the splenic organ in these cases will show a sclerosis, also at times atrophy if splenic decrease in size has been seen.

Infections produce splenic tumors; for instance, protozoal diseases, malaria, kala-azar, etc. Then there are the acute inflammatory tumors of the spleen in bacterial infections, especially typhoid fever, brucellosis, and sepsis. There is a chronic inflammatory enlargement of the spleen in granulomatosis, such as syphilis, tuberculosis, lymphogranuloma. The diagnosis may often be clarified by puncture of the spleen; for instance, one may find the characteristic cells of lymphogranuloma with eosinophiles in the splenic puncture. Upon puncture one may find malaria pigment.

Summary of the Causes of Splenic Enlargement

They may be grouped under the following headings: (1) mechanical obstruction; in other words, venous congestion; (2) infective and toxic conditions; (3) blood diseases; and (4) reticulososes and reticuloendothelioses—with or without disturbance of lipoid metabolism; (5) hemorrhages.

1. Venous or Passive Congestion of the Spleen.—

This may occur rapidly from failure of the right heart or from thrombosis or thrombophlebitis of splenic or portal veins. It may occur slowly from some central cause such as mitral stenosis or incompetence either alone or associated with changes at the tricuspid orifice, adherent mediastinopericarditis, chronic fibroid myocarditis, emphysema of the lung with chronic bronchitis, interstitial pneumonia, or adherent pleurisy.

Additional *local* causes are (1) cirrhosis of the liver; (2) tumors of the liver; (3) chronic inflammatory thickening along the portal tracts, either

syphilitic or tuberculous; (4) pressure upon splenic vein by slowly growing carcinoma of the head of the pancreas; (5) by enlarged lymph glands in the hilum of the liver; (6) aneurysm.

2. Enlargement Due to Acute and Chronic Infective and Toxic Conditions.

—Acute infective and toxic conditions produce enlarged spleen—hyperemic, proliferative, and infiltrative. This acute splenitis on cut section shows the pulp coming off on the knife, the “diffuent spleen.”

Chronic infective enlargements are due to tropical diseases, malaria, and kala-azar, or syphilis and tuberculosis, including in this cirrhosis of the liver.

This initial hyperemia is replaced by hyperplasia of the splenic tissue, especially of the pulp, so that the color is frequently paler than normal, the consistency either normal or a little increased, the capsule thickened. Later, hyperplasia of the stroma occurs with thickening of the organ. The sheaths of the vessels and sometimes the trabeculae show hyperplasia of connective tissue. This may cause atrophy of the cellular constituents in the pulp. Cut sections show distinct mottling with lighter and darker red parts. At times there is marked pigmentation, and frequently there is adherent perisplenitis.

Spleen in Malaria.—There are found acute inflammatory swelling of the spleen and melanin and hematogenous pigment contained in free or fixed phagocytes, or lying free in the sinuses. Parasites are found in the red blood cells of the pulp and in the large phagocytes. In chronic malaria, the spleen is harder from increase of the reticulum, which predominates over the cellular hyperplasia—color is gray brown.

Spleen in Kala-Azar.—Enlargement is associated with marked anemia, leukopenia, skin hemorrhages, local dropsies, and enlargement of the liver, and exceeds enlargement due to malaria. Microscopically, many large mononuclear histiocytic phagocytes, 4 to 5 times the diameter of a red blood corpuscle, are seen containing numerous oval parasites. Other cells of smaller size lying in the pulp contain red blood cells and pigment. In later stages there is considerable increase of the reticulum, especially near the malpighian bodies.

Tuberculosis of the Spleen.—This is secondary, or there may be tubercles from acute miliary tuberculosis or subacute and chronic tubercles with caseation. In children a bovine origin of the infection is suggested.

In acquired *syphilis* the spleen is enlarged, especially in the tertiary stage, with waxy or amyloid infiltration. In congenital syphilis in children enlargement associated with recent or old perisplenitis, accompanied by diffuse fibrosis, endarteritis, and occasionally periarteritis, numerous spirochetes can be demonstrated.

Increase of reticulum is seen in leprosy, with enlargement, perisplenitis, atrophy of malpighian bodies, and disappearance of lymphocytes. There are numerous leprosy cells in clusters.

3. **Splenic Enlargements in Blood Diseases.**—Leukocythemias, splenic anemia and Banti's disease, and polycythemia.

4. **Splenomegalies in the Reticuloses and Reticuloendothelioses.**—This includes active hyperplasia of the true reticulum, with changes in follicles of lymph glands and in malpighian bodies of the spleen. In reticuloses, the spleen

may weigh as much as 4.7 kilograms. Red pulp is described with large malpighian bodies, the ordinary lymphocyte being crowded out. Large cells are seen.

The Spleen in Lymphadenoma.—Enlargement is uniform, capsule thickened. Section shows congestion, brownish-red color; malpighian bodies are prominent. There is an accompanying alteration of the lymph glands of the body. Lymphadenoma cells with nongranular cytoplasm and convoluted, indented, or ring-shaped nuclei, closely resembling the giant cells of bone marrow, are present. Eosinophiles are present.

Reticuloses Associated With Disturbance of Lipoid Metabolism.—

a. Gaucher's disease: Spleen may weigh from 3,000 to 4,000 gm. Pulp is infiltrated with Gaucher cells.

b. Niemann-Pick's disease is found in children, especially females, but, in contrast with Gaucher's disease, its course is rapid and leads to death within three years. Lipoids are found in the spleen. Scar formation in the later stages replaces the lipoid formations. These changes must be distinguished from those occurring in amaurotic familial idiocy, known as Tay-Sachs' disease, which may occur simultaneously. The visceral changes in Niemann-Pick's disease do not occur in Tay-Sachs' disease, nor do all cases of Niemann-Pick's disease show the cerebral changes of Tay-Sachs' disease, in which the brain is hard and leathery, the fissures are widened, the corpus callosum atrophied, and fat granule cells collect about the blood vessels.

c. Xanthogranulomatosis is also known as the Hand-Schüller-Christian disease. This disease attacks males and is often associated with exophthalmos and diabetes insipidus. Deposits of cholesterol esters within large phagocytic cells fill multiple defects in the skull; there are also deposits in the white matter of the brain and cord, in periosteum of other bones, in lungs, pleura, liver, lymph glands, bone marrow, and spleen.

5. **Splenomegaly in Presence of Hemorrhages.**—This enlargement and the edematous softening of the spleen occur whenever there have been blood effusions and hemorrhages of any considerable size in any organ or cavity of the body. It is due to increased function, or blood destruction, in the main.

Tumors of the Spleen.—Primary fibroma, chondroma, osteoma, lymphangioma, hemangioma, and melanoma of the spleen have been recorded. Of secondary tumors, sarcomas occur less infrequently than carcinoma. The most common type is melanotic sarcoma.

Animal Parasites.—Most frequent are the hydatids of *Echinococcus granulosus*.

Cysts of the spleen are rare. True cysts come from dilatation of blood spaces, from cavernous angioma, or dermoids; or they may be parasitic. False cysts may be traumatic, due to necrosis with softening, or tuberculous.

Abscess of the spleen is seen from breaking down, as in sepsis.

Gaucher's Disease

In the consideration of Gaucher's disease, one must bear in mind that it belongs to the group of diseases known as xanthomatosis, or a series of clinical

and anatomic conditions in which lipoid substances are deposited in certain tissue systems or organs of the body. Xanthomatoses have been classified as follows: (1) generalized; (2) local.

There are two generalized types, the symptomatic and the essential or primary.

The symptomatic form is seen as multiple xanthomata in diabetes or liver diseases which are associated with jaundice, also in chronic kidney disease. These xanthomata occur as yellow pea-like nodules in the skin. In such cases, lipoid is deposited in proliferating cells of the connective tissue of the skin and in the endothelium of lymph vessels. These large cells contain fat.

The second type of the generalized form, the essential or primary xanthomatoses, comprises Gaucher's disease, Niemann-Pick's disease, Hand-Schüller-Christian's disease, and fourth, the primary nonsymptomatic external and internal xanthomatoses in skin and the inner organs.

Gaucher's disease was first described by Gaucher in 1882. He called it a primary epithelioma of the spleen. In 1900, Bovaird of New York called it a nonneoplastic disease, stating that it was an endothelial hyperplasia in the spleen, liver, and lymph nodes. In 1907, Schlagenhauser called it a systematic affection of the reticulum cells of all lymphatic and hematopoietic organs, including the bone marrow. In 1907, Marchand recognized the importance of the deposit of foreign substances in the histogenesis of the Gaucher cells. In 1916, Mandelbaum and Downey found conception of the origin of these cells. In 1924, Lieb and Epstein, by study of the spleen, showed the lipoidal nature of the Gaucher substance, showing that kersasin is its important constituent. Kersasin belongs to the cerebrosides (sphingogalactides). This disease is not rare. Pick in 1926 collected thirty-nine cases to that date. Cushing and Stout, in the same year, collected in this country fifty cases. Hoffman and Makler¹ collected eighty-nine cases in all, including their own case.

The disease is of familial incidence. Collier first reported its occurrence in more than one member of a family. It is more common in the female.

It is characterized by splenic and liver tumors. The oldest patient of L. Pick was fifty-six years. The bone was involved as noted by pain in the lower ends of the femur and tibia or tenderness over sternum and ribs. The earliest signs are the characteristic pigmentation of the skin and definite blood changes. The skin pigmentation, mostly confined to face, neck, and hands, is yellow brown to ochre. There also occur brownish-yellow wedge-shaped thickenings of the sclerae, the base of the wedge lying toward the margin of the cornea. These pigmentations are expressions of a general hemochromatosis which is constantly present in this disease and becomes more marked with increased duration of its course.

Hematologic Findings. —

The *blood changes* are leukopenia, which may be due to diminution of neutrophiles or lymphocytes, a moderate hypochromic anemia, often a thrombocytopenia, often bleeding from the nose or gums, hematemesis, melena, or uterine bleeding. Even slightest trauma produces a purpuric bleeding. Death

¹Hoffman, S. J., and Makler, M. I.: *Am. J. Dis. Child.* 38: 775, 1929.

is not usually due to cachexia, but more often to an intercurrent disease, such as pneumonia, sepsis, tuberculosis, or carcinoma. Some of these patients die following splenectomy. Bone marrow puncture shows Gaucher type of cell.

Pathologic Anatomy: A very large spleen, weighing as much as 8,100 grams. Cut section shows a reddish-gray, pink, or sometimes chocolate-brown background stippled with innumerable gray-white or gray-yellow markings, corresponding to accumulations of Gaucher cells. Second, small or large nodular cavernous foci form in spleen and are always multiple. Liver may weigh 3,300 gm. Remember the normal weight is 1,500 gm.

The lymph nodes show no enlargement of the superficial glands, but enlargement and pigmentation of the intrathoracic and intraabdominal glands occur. Hemachromatosis of skin, sclerae, parenchyma of spleen, liver, and lymph nodes are also present.

The essential histologic change is the presence of many Gaucher cells which are demonstrable by acid fuchsin stain after picric acid fixation. Cytoplasm is wrinkled giving them a vacuolated appearance. There are arterial branches within the nests of Gaucher cells. Pigment is absent only in children and infants. Owing to the disappearance of Gaucher cells, we see fibrotic nodules. In the liver, the process is cirrhotic and contains nests of Gaucher cells.

The peculiar appearance of the Gaucher cells is due to the presence of kersin, which may be demonstrated chemically even in dried spleens. The formula of kersin given by Rosenheim is $C_{47}H_{91}NO_8H_2O$. It has properties similar to phrenosin, and accompanies phrenosin in tissues of the nervous system, both constituting a cerebroside or glycolipin. Capper, Epstein, and Schless¹ report a case of Gaucher's disease with presentation of a table differentiating the lipid disturbances. This is Table 81 on pages 954 and 955.

Method for demonstration of kersin is given by Bloom and Kern² and is carried out by taking formaldehyde-fixed spleen, or fresh spleen, grinding through a meat chopper, drying to a constant weight in a vacuum desiccator. The dried powder is then extracted for 5 days with ether in a Soxhlet. The residue is extracted with ethyl alcohol at 40° C. for 36 hours. The material is further extracted at boiling temperature in a fresh portion of ethyl alcohol for 5 days. The ether soluble fraction is treated with acetone, the resulting precipitate of phosphatids filtered off, washed with acetone, and dried to constant weight in the vacuum desiccator. The acetone and ether are removed from the filtrate, and the residue, containing cholesterol and fatty acids, dried to constant weight.

That part of the precipitate from the 40° C. alcohol fraction is dissolved in 100 c.c. of alcohol, to which are added 30 c.c. of cold saturated mercuric chloride. This gives a colorless gelatinous precipitate, much like egg white in appearance, which fills the entire solution. The precipitate is removed by filtration and suspended in methyl alcohol; hydrogen sulphide is passed through the suspension. The precipitate is filtered off, the filtrate boiled with charcoal and filtered again. This filtrate when concentrated and cooled gives an almost white, gelatinous precipitate. Under the microscope this appears as round crystals arranged radially about a nucleus. On hydrolysis of the material for 8 hours in methyl alcohol and sulphuric acid under a reflux condenser, a white, crystalline material with a melting point of 56.7° C. is obtained, which corresponds very closely to that of the methyl ester of lignoceric acid.

TABLE 81.—XANTHOMATOSSES OR LIPOIDOSES—DISEASES DUE TO DISTURBANCES IN LIPOID METABOLISM*
(Rowland.) (Pick.)

NAME	TYPE OF LIPOID	BLOOD FINDINGS	EYE-GROUNDS	SPLEEN, LIVER GLANDS	AGE	BONES	PATHOGNOMONIC FEATURES	SKIN	TREATMENT	REMARKS
A. Gaucher's disease (90-100 cases)	Cerebrosid (kerasino-sphingogalactid)	1. Hypochromic anemia 2. Leukopenia 3. Thrombopenia 4. Later, hemorrhagic diathesis	Negative	Spleen markedly enlarged Liver enlarged Slight or no lymphadenopathy	Infancy to adult life	Mottling and rarefaction with cortical thinning, flasklike appearance ends of femora	1. X-ray appearance of long bones, especially femora 2. Splenic puncture 3. Bone-marrow examination	Subicteric pigmentation of exposed parts in 45%. Yellow thickened pingueculae in eyes in 15%	Splenectomy (fatal in 20%) or radiation (both palliative)	Common in Jews
B. Niemann-Pick's disease or lipoid histiocytosis (Bloom)	Phosphatids	1. Moderate secondary anemia 2. Slight leukocytosis 3. Vacuolization of non-granulated cells 4. Excess of lipoids in blood	Cherry-red spot in macula occasionally found	Spleen and liver very large Moderate lymphadenopathy	Infancy	Any bones or organs may be invaded by the foam cells	Splenic puncture	Brownish-yellow discoloration	No treatment, all fatal	Mental retardation may be present resembling Tay-Sachs' disease. Most common in Jews

C. Hand-Schüller-Christian disease (45-50 cases)	Cholesterol and its esters	There may be a hypercholesterolemia	Negative	Not enlarged	Any age	Membranous bones involved	1. Defects in membranous bones 2. Diabetes insipidus 3. Exophthalmos 4. Gingivitis and stomatitis 5. Adiposogenital dystrophy	Negative	X-ray treatment of involved area causes prompt local healing but does not stop the progress of the disease	Brain shows prelipoid deposits in granular layer and about dendrites of the Purkinje cells. Most common in Jews
D. Tay-Sachs' disease or amaurotic familial idiocy	A pre-lipoid	Negative	Cherry-red spot in macula lutea usually found	Usually negative	Infancy	Not involved	1. Eyegrounds 2. Mental retardation 3. Hyperacusis	Negative	All fatal	
E. Xanthomatoses of skin, etc.	Cholesterol and its esters	Negative	Negative	Negative	Any age	Any bones may be involved	-----	Xanthomatoses of any part of skin	Excision, if tumorous	

*Capper, Epstein and Schless: Am. J. M. Sc. 188: 84, 1934.

It is interesting to note that Gaucher cells arise from the endothelium of blood vessels. It is evidently a primary disease of the reticuloendothelial system, based upon an error in metabolism. The pigmentation is due to the fact that lipoid-storing cells of every sort show a tendency to store simultaneously hemoglobinogenic pigments; with stimulation of the reticuloendothelial structures, there is an increased hemosiderosis, that is, an increased blood destruction. The mild anemia, which is constant in this disease, is due to the bone marrow penetration by the Gaucher cells.

The bony changes are demonstrable by roentgenologic examination.

The **blood picture** shows a low hemoglobin and a low red blood cell volume. The following hemogram is illustrative of Gaucher's disease:

Hemoglobin, 44 per cent; red cells, 3,628,000; white cells, 2,650. Neutrophils 49 per cent; lymphocytes 38 per cent; eosinophiles 5 per cent; monocytes 8 per cent; basophiles 0; blood platelets 30,000.

The anemia in this disease is not as well marked as it is in Banti's disease.

Niemann-Pick Disease

This disease is similar to Gaucher's disease from a histologic standpoint. It is a typical disturbance of the histiocyte apparatus. There is a great enlargement of the liver, a change which occurs much more rapidly than it does in Gaucher's disease.

The blood picture is similar to that of Gaucher's disease.

Anatomically, Niemann-Pick disease differs from Gaucher's disease in that the characteristic cells are much more prevalent in the spleen, liver, lymph glands, and bone marrow. Reuben maintains that the anemia of Niemann-Pick disease is not as severe as that of Gaucher's disease, nor is the leukopenia as pronounced. He also states that the qualitative leukocytic blood picture is unchanged. Moschokowitz reported a case with 33 per cent hemoglobin, 1.6 million red cells, and 6,500 white cells, of which 90 per cent were neutrophils. According to Reuben the prognosis in children is more severe than in adults, and it is a more rapidly fatal disease. It seems to be associated with delayed development of the blood.

RELATIONSHIP OF THE LIVER TO BLOOD DISORDERS AND DISEASES OF THE RETICULOENDOTHELIAL SYSTEM¹

The liver participates in blood disorders by virtue of its function as a reticuloendothelial organ, its role in the metabolism of blood pigments, in the storage of iron, in the synthesis of blood proteins, and in the storage of the anti-pernicious anemia factor. Furthermore, the spleen, which participates in so many blood dyscrasias, bears an intimate relationship to the liver both physiologically and pathologically.

In most blood dyscrasias, the liver is affected to some extent, and it may be markedly enlarged. However, liver function is seldom significantly impaired. Green and Conner in 1926 and other investigators since then have shown that all of the commonly used liver function tests usually give normal results in cases of hepatomegaly due to leukemia, polycythemia, hemolytic jaundice.

¹Reinhard, Edward H.; Bull. St. Louis M. Soc., May 11, 1945; Lab. Digest 9: 3, 1945.

pernicious anemia, and even Gaucher's disease. In polycythemia the liver is frequently enlarged due to chronic hyperemia, in leukemia there may be marked infiltration of the liver with leukemic cells, in pernicious anemia the hepatomegaly which is sometimes seen is due to fatty changes and hemosiderin deposits, while in Gaucher's disease, Hodgkin's disease, lymphosarcoma, and several other diseases of the reticuloendothelial system striking pathologic changes may be found in the liver. The fact that these diseases rarely result in any significant impairment of liver function either clinically or by laboratory testing is a manifestation of the great reserve power of the liver.

Jaundice is common in the blood dyscrasias, and this sometimes leads to an incorrect diagnosis of primary hepatic or biliary tract disease. In congenital or acquired hemolytic icterus, the jaundice is obviously due to the rapid breakdown of red blood cells as a result of either an inherent fragility of the erythrocytes or possibly due to the action of a hemolysin. In pernicious anemia the characteristic lemon yellow color is due either to an abnormality of pigment metabolism or to hemolysis.

Rich and associates have suggested that in any hemolytic anemia the jaundice may be due to a combination of rapid disintegration of erythrocytes with hepatic lesion. It is very difficult to produce jaundice in a dog by the injection of bilirubin. Furthermore, Rich showed that simple hemorrhage in dogs as well as pernicious anemia and secondary anemias in human beings may be accompanied by damage to the cells around the efferent veins of the liver lobules. This lesion is identical with that seen in chronic passive congestion of the liver, and Rich postulated that the lesion is due to tissue anoxia resulting from the anemia. The jaundice is thus due to a combination of hemolysis plus functional liver damage. In human hemolytic anemias, a hepatic lesion is not always demonstrable histologically, but it is probably true that a perfectly normal liver can excrete all the bilirubin the body is capable of producing; hemolysis alone, therefore, probably cannot produce jaundice unless the liver is functionally deranged.

In leukemia, as well as in the so-called lymphomas, mild jaundice sometimes occurs due to infiltration of the liver or destruction of liver cells by the lymphomatous process. Occasionally enlarged lymph nodes in the portal fissure may occlude the bile ducts and produce marked jaundice. Jaundice due to this mechanism may be completely relieved by x-ray therapy directed to the upper abdomen.

Hemorrhagic Disorders Due to Diseases of the Liver or Biliary Tract.—In any hemorrhagic disease there is always either a defect of capillary permeability or a defect in the coagulation mechanism. So far as is known, the liver has nothing to do with capillary permeability, but the liver does contribute to blood coagulation. There are four essential substances which must be present in order for blood to coagulate normally; these are thromboplastin, Ca ions, prothrombin, and fibrinogen. Of these, fibrinogen is probably synthesized solely in the liver, whereas prothrombin is synthesized primarily in the liver. Thus, theoretically, liver disease may result in hemorrhage due to failure of synthesis of either of these factors.

Actually, a condition known as congenital fibrinopenia has been described in which there is a congenital specific defect in the ability of the liver to synthesize fibrinogen; however, only half a dozen cases have been described. The amount of fibrinogen normally present in the plasma is far in excess of what is required for coagulation. In any kind of severe liver disease, the plasma fibrinogen level may be decreased below normal, but this is always overshadowed by the much more marked and more significant decrease in prothrombin.

One of the factors that may produce bleeding due to inadequate amounts of prothrombin in the blood is vitamin K deficiency. Dietary deficiency never produces vitamin K deficiency in adult human beings, as proteolytic bacteria in the intestines can synthesize all the vitamin K that is required. However, during the first few days of life there are few if any bacteria in the intestines and in the newborn infant prothrombin deficiency is common. This is generally accepted as being the principal factor responsible for hemorrhagic disease of the newborn.

In adults, vitamin K deficiency occurs only when there is poor absorption from the intestinal tract due either to severe diarrhea or to absence of bile salts in the gut. Vitamin K is fat soluble and is not absorbed in the absence of bile salts. Thus, the bleeding which occurs in severe obstructive jaundice can be corrected either by the parenteral administration of vitamin K or by the administration of bile salts by mouth.

In contrast with this type of prothrombin deficiency, the prothrombin deficiency resulting from severe liver damage is not affected by vitamin K administration. When the liver cells which synthesize prothrombin are destroyed, the only rational therapeutic approach is to keep the patient alive by supplying prothrombin from without in the form of plasma transfusions. This only stops the bleeding temporarily, but is an extremely important procedure whenever the nature of the liver disease is such that regeneration of liver tissue is possible.

A condition known as congenital hypoprothrombinemia has been observed in a few children in which the liver lacks the ability to synthesize prothrombin. There have been very few cases of this sort reported in the literature, but now that it is being looked for, it is being recognized more frequently. Quick stated that he has knowledge of over half a dozen such cases himself.

The Role Played by the Liver in Certain Anemias.—The liver plays an important part in two types of anemia—pernicious anemia and iron deficiency anemia. It is well established that the erythrocyte maturation factor is stored in the liver, and the liver of patients with pernicious anemia lacks this substance. It has been shown that cirrhotic livers are deficient in erythrocyte maturation factor. It is, therefore, very easy to assume that the anemia so commonly seen in various types of liver disease is merely due to the absence or diminished quantity of this factor in the liver. It is known that some degree of anemia is usually present in advanced cirrhosis of the liver. But perhaps sufficient emphasis has not been placed on the fact that in only about half of these cases is the anemia macrocytic. The mean corpuscular volume in general is in the vicinity of 100 cubic microns; however, the macrocytosis does seem to increase as the anemia becomes more marked. The anemia of cirrhosis is often accompanied by a reticulocytosis and occasionally by mild leukopenia.

It has frequently been suggested that because of the close resemblance of the blood picture to that of pernicious anemia, the damaged liver is responsible for a deficiency of antipernicious anemia factor. A reticulocyte response to the administration of liver extract does occur in some of these cases, but in other cases of cirrhosis no such effect is obtained. It is probable that the anemia of cirrhosis and other types of severe liver disease is not due to deficiency of the erythrocyte maturation factor. It is important to remember that macrocytosis which is so characteristic of pernicious anemia also occurs in the anemias of chronic uremia and occasionally in leukemia. Furthermore, in normal animals the kidney as well as the liver contains large amounts of anti-pernicious anemia factor and, thus, it is hard to see how liver disease alone could produce a significant decrease in the amount of available erythrocyte maturation factor unless the kidneys were simultaneously damaged.

Castle studied the macrocytic anemias due to nutritional deficiency. In two of the three patients he studied, the anemia developed during pregnancy. In spite of the fact that the anemias in all three of these patients were strikingly macrocytic, no reticulocyte response occurred in any of them following the intramuscular injection of liver extract. In all three cases, however, a reticulocyte response followed by gradual rise in red blood counts occurred when liver extract was given by mouth. Castle concluded that the "unitarian" hypothesis which regards all macrocytic anemias as being due to deficiency of the erythrocyte maturation factor is not tenable. He suggested that in this type of nutritional macrocytic anemia the digestive organs form a new hematopoietic substance from the liver extract in a fashion analogous to the food-gastric factor relationship in true Addisonian pernicious anemia. Present evidence does not justify the conclusion that all macrocytic anemias are due to the same mechanism; there is no conclusive proof that the macrocytic anemia of liver disease is due to deficiency of the anti-pernicious anemia factor.

When red blood cells are hemolyzed in the body, the hemoglobin is broken down and the iron thus liberated is stored in the reticuloendothelial tissues throughout the body. The liver is perhaps the most important of all the organs which store iron. By virtue of this storage mechanism, extremely minute quantities of iron are lost from the body by excretion. It is for this reason that hypochromic microcytic anemia due to iron deficiency practically never occurs except in hemorrhagic states where large amounts of actual hemoglobin are lost from the body. Hypochromic microcytic anemia due to iron deficiency very rarely, if ever, occurs as a result of inadequate intake of iron in the diet. Thus, the liver plays an important part in iron metabolism.

THE SEDIMENTATION RATE OF ERYTHROCYTES*

John Hunter in 1797 is given the credit of first noting that the speed of sedimentation of the erythrocytes was increased in individuals suffering from inflammatory lesions and that this speed varied with the severity of the infection. Others (Nasse, 1836; Davy, 1839; Muller, 1844) noted the behavior

*Part of this section is from a monograph by R. B. H. Gradwohl, "The Rediscovery of Blood Sedimentation Test," *Rev. de med. Trop. y Parasit. Bacteriol.* 8: 295, 1937.

of red cells but did not explain it. Interest was renewed by Fahraeus¹ in 1917. In 1920 Linzenmeier² worked out a technic. In this country, Friedlander,³ Polak and Mazzola,⁴ Baer and Reis⁵ reported the value of the test in obstetrics and gynecology. Gruenfeld,⁶ Cutler,⁷ Bach and Hill,⁸ Bannick,⁹ and others have called attention to its usefulness in medical cases, particularly rheumatic fever and tuberculosis. Grodinsky, Lesser and Goldberger, and Smith have written of its advantages in general surgery.

Sedimentation of the erythrocytes is a very complex biological process, the basic mechanisms of which cannot be reduced to a common denominator. Fahraeus referred to the phenomenon as "suspension instability," which is still a good description. The physicochemical forces which have been implicated are numerous and varied. The electrical charge of erythrocytes as related to proteins has been thought to play a role. Hoeber, Mond, and Ley note that hydrogen ion concentration influences the rate, with acidosis slowing and alkalosis accelerating it. The plasma proteins exert an influence on the sedimentation rate. Fibrinogen is perhaps the most readily demonstrable protein affecting sedimentation. In diseases associated with hypofibrinogenemia, such as liver disease, the rate is very slow and some observers have suggested that the sedimentation test be included in liver profile studies. The addition of fibrinogen to normal blood in vitro markedly accelerates settling of the erythrocytes. A. J. Meyers and co-workers¹⁰ confirm this fact by in vitro experiments and call attention to alpha-2 globulin and gamma globulin as other protein fractions having a similar effect. These workers emphasize that the erythrocyte sedimentation rate alone "does not give any clue as to the level of any one of the responsible factors." They offer two complex formulas based on plasma:cell ratio and plasma protein concentrations from which formulas they can predict the sedimentation rate. The concentration of proteins, perhaps qualitatively as well as quantitatively, in some unknown manner affects the aggregation of erythrocytes in the form of rouleaux or agglomeration.

The specific gravity of plasma does not play an important role because the addition of weak saline causes a diminution in sedimentation rate.

A purely physical factor in sedimentation rates can be readily demonstrated and is now common knowledge. If one sedimentation tube is set up perfectly perpendicularly and another tube of the same specimen is aligned at an angle, the latter will have a higher speed of sedimentation than the former. The temperature under which the test is performed affects the rate, the rate tending to be elevated as the temperature rises. These two factors are important controls in performing the test.

Technic of Determining Sedimentation Rate of Erythrocytes

Materials.—

Westergren Method

Westergren pipette, 200 mm. in length, 2.5 mm. diameter, graduated in mm.

Westergren block.

Tourniquet.

Sterile 2 c.c. syringe.

Sterile 3.7% solution of sodium citrate.

Alcohol, sterile sponges, adhesive tape.

Watch glass.

Fig. 224.—Westergren sedimentation apparatus, improved Hellige model. (Hellige, Long Island City, N. Y.)

Fig. 225.—Rack, Linzenmeier or Cutler sedimentation tubes. (Hellige, Long Island City, N. Y.)

Technic.—

Draw sodium citrate solution into the syringe to the mark 0.4.

Apply the tourniquet to the patient's arm, and locate the vein.

After disinfecting the skin, insert the needle into the vein and draw blood into the syringe up to the mark 2 c.c. Remove tourniquet and withdraw the needle.

Remove needle from syringe.

Draw back the plunger of the syringe, and tilt back and forth several times to insure a good mixture of the blood and citrate.

Eject contents of syringe into watch glass.

Draw the mixture into a Westergren pipette to the mark 0, and place the pipette in a Westergren block in a vertical position.

The number of millimeters that the erythrocytes drop in the pipette is the sedimentation rate.

Read the sedimentation of the erythrocytes in mm. at the end of 1 hour.

Normal.—After 1 hour, 1 to 15 mm. for men; 0 to 20 mm. for women.

Linzenmeier's Method**Materials.—**

Tubes 5 mm. in diameter, 65 mm. in height, with two marks, one at the level of 1 c.c., the other 18 mm. below this. Other equipment same as above.

Technic.—

Draw 0.2 c.c. of 3.7% sodium citrate solution and 0.8 c.c. blood into the syringe and mix.

Pour the mixture into the tube, up to the 1 c.c. mark.

Allow to stand in an upright position until the red blood corpuscles have settled to the mark 18 mm.

Note the time for this to take place. Record in minutes.

Normal.—Healthy men, from 350 to 600 minutes; healthy women, from 300 to 600 minutes. Menstruation 600 minutes. Anything under 200 minutes is pathologic.

Fig. 226.—The Linzenmeier, Cutler, and Wintrobe tubes.

Materials.—**The Graphic or Cutler Method**

Tubes 5 c.c. capacity, graduated in 0.1 c.c., each 0.1 c.c. 1 mm. in height.

Sterile 5 c.c. syringe.

Freshly prepared 3% sodium citrate solution, sterile.

Other equipment same as above.

Sedimentation report charts which may be purchased from Charles M. Berkemeyer, Sellersville, Pa., and from Clay-Adams Co., Inc., 44 East Twenty-Third Street, New York, the A. S. Aloe Co., St. Louis, and other supply houses.

Technic.—

Draw into the syringe 0.5 c.c. sodium citrate solution.

Draw blood to mark 5 c.c.

Mix as above.

Pour contents into sedimentation tube.

Stopper with a paraffin-coated cork.

The tubes are allowed to stand 10 hours, but must be observed every 5 minutes for one hour.

Fig. 227.—Cutler chart.

Draw curve on sedimentation chart.

The sedimentation value, determined by the sedimentation of the red cells in the first hour, depends upon the sedimentation graph, the sedimentation index, and the sedimentation time. There are four graphs, two straight lines, and two curves. They are called "horizontal" line, "diagonal" line, "diagonal" curve, and "vertical" curve.

Sedimentation index is the total sedimentation of the red cells at the end of sixty minutes expressed in millimeters.

Normally in men it varies from 0 to 8 mm., average 3 to 4; healthy women, 0 to 10 mm., average 5 to 6. In menstruation as high as 12 mm.

Wintrobe and Landsberg Method

Materials.—

Wintrobe tubes and venous blood collected in 3:2 oxalate mixture (see page 567).

Place the filled Wintrobe tube (see Fig. 226) in an exactly vertical position, at room temperature, and observe the point on the mm. scale to which the corpuscles fall during one hour.

The **normal average** sedimentation in one hour by this method is 3.7 mm. for healthy men, and 9.6 mm. for women, with a maximal range from 0 to 9 mm. for men and 0 to 20 mm. for women.

Comment: For many years it was recommended that the sedimentation rate be corrected for the volume of packed red cells. Wintrobe now feels that this adjustment is an unnecessary refinement of the procedure.¹

Landau Method²

Modification of Linzenmeier-Raunert Method

Before using, the sedimentation pipettes should be well cleaned with alcohol and ether and should be dried thoroughly in an oven or other warm place. If they are not completely dry, sodium citrate solution should be drawn up before the blood test is taken.

Insert capillary pipette into a precision syringe.

Draw up 5% sodium citrate solution by turning the top screw to the left until the upper meniscus of the solution has reached the lower mark *A*.

Lance finger tip or ear lobe of the patient deeply enough to get an even flow of blood without squeezing.

Draw up the blood until the height of the liquid reaches the upper meniscus of the upper graduation *B*, and try to avoid the formation of air bubbles rising in the blood solution. If bubbles should form during the test, they can easily be expelled by means of the top screw. The suction of the blood sample can easily be performed with one hand, by holding the syringe with the capillary pipette in dagger fashion with the middle, fourth and small fingers and manipulating the top screw with thumb and index finger.

Clean the tip of the capillary pipette with ether and continue to draw up the mixture into the bulb (by turning top screw to the left) until the lower meniscus of the blood column ends just a few millimeters below the lower opening of the bulb. (Do not draw blood into bulb completely.) The pipette may then be carefully shaken.

Force the blood up and down twice very slowly by turning screw to the left or right, respectively, in order to obtain a better mixture in the bulb. Force the blood gradually back into the capillary tube, close lower opening with thumb and hold pipette firmly while turning the syringe carefully, exerting a slight pull in order to lift out the capillary pipette which is then placed into the metal stand.

The blood mixture may hang at any place in the tube but should not touch the bottom. Citrated blood should always be drawn slowly into the capillary tube, otherwise part of it will cling to the walls and air bubbles will form. If air bubbles have formed in the blood column, turn syringe upside down at an angle and force out the air bubbles by turning the screw to the right. This will push the blood column toward the opening of the pipette and thereby expel the air bubbles without the loss of much blood.

The instrument consists of a metal stand which holds either six or twelve capillary pipettes, 12 cm. long with an inside diameter of 1 mm. Each pipette is provided with two graduation marks, one at 12.5 and the other at 62.5 mm. above the tip. The pipettes are

¹Wintrobe, M. M.: Personal communication, November, 1954.

²Landau, A.: *Am. J. Dis. Child.* 45: 691, 1933.

held in place by strong bottom springs which press the pipette against corresponding cavities provided in the screws, which are fitted into the upper part of the metal stand directly vertical above the bottom springs.

To insert the pipettes into the stand, press down with the tip of the pipette against the bottom spring, and while holding it down, insert the upper part of the pipette into the cavity, by gradually releasing the pressure on the spring. In the upper part of the pipette is a small bulb similar to the bulb in an ordinary blood pipette.

Fig. 228.—The Landau modification of the Linzenmeier-Raunert blood sedimentation outfit.*

The precision syringe consists of a metal barrel with ground-in plunger which is adjusted by means of a screw. The lower part of the barrel has a perforated rubber stopper fitted inside into which a capillary pipette can be inserted. By adjusting the bottom screw, the size of the perforation of the stopper can be increased or decreased. Near the bottom, the barrel of the syringe has a fine opening in the side which ordinarily is covered with a piece of rubber tubing. Before inserting the capillary pipette, which already has been filled with citrated blood, into the syringe, it is necessary to roll upward with the thumb the pointed part of the rubber tubing and thus expose the side opening of the metal cylinder ordinarily covered by the tubing. By covering the tip of the capillary pipette with the finger, the pipette may be inserted into the syringe as far as it will go, and then the rubber tubing released. In keeping the side opening of the pipette exposed, an excess of pressure in the syringe can be avoided which would tend to expel the blood. In the event that the capillary pipette has a very small outside diameter, the rubber stopper in the syringe may have to be exchanged for one with a smaller opening. If the plunger should fit too tightly, a drop of oil, dropped into the cylinder's upper part, will usually make it slide smoothly again.

The metal housing with a capacity of six capillary pipettes is protected by a velvet-lined case which also holds glass vials for ether and 5% sodium citrate solution and automatic

*This may be procured from Clay-Adams Co., Inc., 44 East 23rd St., New York, N. Y.

blood lancet, rule, rubber tubing, compartment for the precision syringe and room for cotton and compressors. The stand, together with glass capillary pipettes, can be placed in horizontal position in the case.

Results.—

Readings are to be made in millimeters after one hour. The original length of the blood column is 62.5 mm.

Because of the length of the bulb, when using the precision syringe, only very little citrated blood will cling to the walls of the capillary pipette; thus the definite length of the column would deviate only one or a few millimeters at the most from the original length, and this small difference would be of no practical importance. One can also determine the length of the column as approximately 60 mm.

Normal Values.—For children under 2 years, and for men, from 1 to 5 mm. per hour. For children over 2 years, and for women, from 1 to 8 mm. per hour. Slightly increased values are from 6 to 14 mm. and from 9 to 14 mm., respectively. Fairly high values are from 15 to 25 mm. High values are over 25 mm.

The Landau modification of the Linzenmeier-Raunert method of sedimentation is especially useful in pediatrics since it does not entail venepuncture. Venepuncture in children is often attended with difficulties; therefore, any method which avoids it is to be recommended.

Fig. 229.—Walton rack and tubes. (Hellige, Long Island City, N. Y.)

Materials.—

Walton Modification² of the Cutler Method

Tubes 60 mm. long. The internal diameter is such that a tube contains 1 c.c. within the graduated portion, which is divided from 0 to 32.5 mm. in 0.5 mm. divisions, with every tenth line numbered.

3.7% solution of sodium citrate.

5 c.c. syringe.

Technic.—

Exactly 0.5 c.c. of a sterile 3.7% solution of sodium citrate is drawn into a clean sterile 5.0 c.c. syringe.

Syringe is filled to the 5.0 c.c. mark with venous blood from the cubital vein.

Empty syringe into small, clean, dry tube, and gently mix with citrate by inverting a few times.

If patient's erythrocyte count is between 4,500,000 and 5,000,000 no correction need be made. Draw the blood from the vial to the 20 mm. mark on the sedimentation tube and place in upright position.

²Walton, A. C. R.: J. Lab. & Clin. Med. 18: 711, 1933.

Correction of this procedure with variations in the red cell count: If count is above 5,000,000, plasma must be added; if the count is low, plasma must be removed. The amount to be added or removed can be determined by the following formula:

$$\frac{X}{Y} - 1 = \text{amount of plasma to be added to (or removed from) 1 c.c. of blood.}$$

X = number of million cells per cubic mm.

Y = desired number of million cells per cubic mm.

Thus if a patient has an erythrocyte count of 4,000,000 the calculation would be

$$\frac{4.0}{5.0} - 1 = - 0.2 \text{ c.c.}$$

or 0.2 c.c. of plasma per 1.0 c.c. of blood would be removed after centrifuging down the cells. If a count should be 5,400,000 the calculation is

$$\frac{5.4}{5.0} - 1 = + 0.08 \text{ c.c.}$$

or 0.08 c.c. of plasma should be added to each c.c. of blood. The plasma is obtained by centrifuging about 1 c.c. of blood and pipetting off the required amount of plasma.

At the end of one hour the amount of sedimentation is measured from the bottom of the meniscus of the supernatant plasma to the top of the red cell column.

Results.—

Normal sedimentation rate is never above 8 mm. During menstruation women may have a sedimentation rate of 8-12 mm. During pregnancy the rate may go to 14 mm. In the absence of menstruation or pregnancy a rate of over 8 mm. indicates the existence of a pathologic condition.

Balachowsky Method

This is called the sedio-tassometer of Balachowsky. The instrument is designed for ten or less simultaneous determinations. It is composed of a frame bearing the pipettes in spring clips. The frame rests on a support provided with four adaptable screws and a water level to assure absolute perpendicularity. The frame revolves on an axis and can therefore take two positions: the horizontal position and the vertical or working position. Different types of pipettes are furnished (a) one with 100 mm. graduation, reading the sedimentation in millimeters; (b) with six marks between 18 and 36 millimeters; (c) without any division, taking the readings with a centimeter tape.

Fig. 230.—Balachowsky blood sedimentation apparatus (Heilige, Long Island City, N. Y.).

The top part of each pipette is provided with a suction tube composed of two parts: a rubber muff permitting the filling of the pipette with blood and to raise its upper level to the desired height and a suction screw embodied in the rubber muff, with which to bring the level of the blood column to precisely the required point "1" of the graduation, thus making the speed reading very easy.

Technic.—

Test the rocking frame, the suction screw, and rubber muff. Rinse a pipette with 5% neutral solution of potassium oxalate. Expel this fluid and take up the blood from a finger prick, avoiding air bubbles. Place pipette on the frame in the first position; fill as many more pipettes as is necessary to make the requisite number of tests. Compress and release slowly the suction tubes on the pipettes in order to allow the blood its full homogeneity. Turn the frame into a vertical position and note time. After 20 and 30 minutes read the sedimentation rate per hour. Do not use any pressure on finger in taking the blood.

Rourke-Ernstene Method¹

Normal Values: 0.05 to 0.40 mm. per minute.

Material Required.—

Sedimentation tube 120 mm. long with 2 mm. divisions from 0 to 100 mm. Internal diameter of tube, 4 mm. The Wintrobe tube may be substituted here.

Blood sample collected in heparin or "3:2" oxalate mixture.

Technic.—

Fill the sedimentation tube with the blood sample to the 0 mark.

Place the tube in a suitable rack in a vertical position.

Take 6 to 10 readings at regular intervals, until the readings indicate marked slowing in rate of settling of the erythrocytes.

Calculation.—

The calculations may be made either by using the data as recorded or by preparing a curve. Take the figures only during the period of *fastest* rate of fall, which usually eliminates the first 10 to 15 minutes, and the later period of observation.

Divide the total fall in mm. during the fastest period of fall by the time required for the fall. Express the result in mm. per minute.

Example.—

Time in Minutes	5	10	15	20	25	30	35	40	45	50	55	60
Readings in mm.	2	3	6	9	15	22	29	34	36	38	40	41

The fastest fall is between 20 and 40 minutes, 25 mm.

$$\text{Sedimentation index} = \frac{25}{20} = 1.25 \text{ mm./min.}$$

Summary of the Pertinent Facts on the Sedimentation Test**Normal Values.—**

Westergren: Men: 0 to 15 mm. after one hour

Women: 0 to 20 mm. after one hour

Linzenmeier: Men: 350 to 600 minutes

Women: 300 to 600 minutes

Under 200 minutes is pathologic

Cutler: Men: 0 to 8 mm. after one hour (3 to 4 mm. in one-hour average)

Women: 0 to 10 mm. after one hour (5 to 6 mm. in one-hour average)

Wintrobe and Landsberg: Men: 0 to 9 mm. in one hour (3.7 mm. average)

Women: 0 to 20 mm. in one hour (9.6 mm. average)

Landau: Men: 1 to 6 mm. in one hour

Women: 1 to 9 mm. in one hour

Walton: Men and women: never over 8 mm. in an hour.

Comments on Sedimentation Rate Determination.—

Peightal² very properly believes that the test is not a specific diagnostic sign for any disease, but indicates the presence or absence of an inflammatory process. In some conditions it may be used in part to estimate the severity

¹Rourke, M. D., and Ernstene, A. C.: *J. Clin. Invest.* 8: 545, 1930.

²Peightal, T. C.: *New York J. Med.* 36: 173, 1936.

of an infection. In diseases of the pelvis a careful history and physical examination are necessary to exclude the presence of infection elsewhere; the examiner must remember that infected sinuses and teeth as well as acute rheumatic fever, tuberculosis, etc., cause rapidity of sedimentation. Pregnancy increases the rate very much. The increase is gradual from the third month until the ninth month, when it may be five times the average normal. This change in rate disappears four weeks post partum.

It is in the differential diagnosis of conditions causing pain in the right lower quadrant that the sedimentation test furnishes a very definite aid, particularly within the first forty-eight hours of the onset of symptoms. Grodinsky, Lesser and Goldberger, and Smith have shown that the sedimentation rate remains approximately normal in acute appendicitis for at least the first forty-eight hours from the onset of symptoms, and during the catarrhal, suppurative, and even gangrenous stages. Increased rates are observed only in localized abscess or general peritonitis. In cases of acute salpingitis, before one recognizes the swollen tube by bimanual examination as a palpable mass, only tenderness and spasm being revealed, the sedimentation rate is markedly increased (50 to 100 mm. in an hour). Thus in this test there is a factor in differentiation between acute appendicitis and early acute salpingitis. It must be emphasized that when the disease process produces a palpable mass, one cannot distinguish between appendiceal and tubal conditions just by the sedimentation rate, for abscess of the appendix may give a rate equal to that of the infected tube. If, however, abscess of the appendix can be ruled out in any case of pelvic mass, then the sedimentation test becomes an important adjunct in ascertaining the nature of that mass. With regard to salpingitis, unruptured ectopic pregnancy, twisted ovarian cyst, hemorrhage into a large graafian follicle or cyst, and painful ovarian swelling related to ovulation, one must consider the history and pelvic examination by far the most important factors in making the correct diagnosis, while temperature, blood count, Aschheim-Zondek test, and sedimentation rate only help to influence the opinion. A swollen inflamed tube may show a sedimentation rate of from 50 to 100 mm. and a time of 30 to 50 minutes, while an unruptured ectopic pregnancy with very little or no blood in the peritoneal cavity will have a rate between 20 to 35 mm. and a time of 100 to 120 minutes. A twisted ovarian cyst may cause a very high sedimentation rate if there has been much interference with the circulation of the tissue, while hemorrhage into the follicle or cyst and painful ovarian swelling usually cause no increase in the rate.

The test has been of great benefit in prognosticating the degree of healing in salpingitis or postabortional infections and in indicating the proper time to operate. Previously, dependence was placed upon the temperature curve and leukocyte count for this information. Consequently, patients with pelvic infection were allowed to get out of bed too soon and had relapses, or operations were performed in the "too acute" stage. It was found that the temperature curve and leukocyte count return to normal often many days before the sedimentation rate has been materially reduced. By keeping patients with acute salpingitis in bed until the sedimentation rate falls below 30 mm. in an

hour, there is practically no relapse. The same figure is used in deciding upon operability of chronic tubal disease. This avoids abdominal operation in the "too acute" stage, and postoperative convalescence is far smoother.

Landau,¹ in discussing the usefulness of microsedimentation rate in pediatrics, emphasizes its employment in arthritic and tuberculous conditions. In a number of cases, the test was useful in children, bedfast for a long time, whose primary illnesses during their stays at the hospital were followed by regularly made microsedimentation tests. In such cases an increase in sedimentation rate occurred as the symptom of a complication several days before a rise in temperature occurred. Usually the microsedimentation decreased much later than the temperature fell, sometimes reaching the desired value only several weeks after the temperature had become normal. Westergren considers pronounced sedimentation to be characteristic of acute polyarthritis. High values in light cases of acute polyarthritis are important as an indicator of the intensity of the process of the disease. Not until sedimentation has reached normal values after repeated tests can one regard the infectious process as having run its course. Since, apparently, rheumatic illnesses are very common in Gothenburg, Sweden, Landau had numerous opportunities of testing this method in such cases. He found it quite useful in following the progress of acute polyarthritis, acute endo-, peri-, and myocarditis, and in chorea. He has found this test very helpful in facing this important question: When, after the temperature has subsided to normal, can one venture to pronounce the endocarditic process ended in acute endocarditis? In other words, when does the endocarditis end and the vitium, the resultant condition, begin? This also raises the important question of the continued therapeutic regimen, particularly physical therapy, as well as the prognosis for cardiac function. Landau states that, in addition to cases in which the diagnosis is doubtful, microsedimentation has proved to be of extraordinary value as an indicator of disease, being generally far more sensitive than the body temperature. In routine treatment of acute polyarthritic and cardiac diseases at the Gothenburg Hospital for children, it was his custom not to release patients from bed until microsedimentation had shown normal values after repeated tests, irrespective of whether or not the body temperature had become normal. We do not agree that such rigidity in management is necessarily wise and that return to activity can be judged by the sedimentation test *alone*. The *total* clinical picture must be taken into account for such decisions.

In a study of 25 cases of chorea it was found that when chorea had existed as the only rheumatic condition, or in which polyarthritis or endocarditis had preceded it so long before that chorea could not be considered as having arisen in direct connection with these diseases and in which complicating commonplace infection could be precluded, repeated microsedimentation tests showed low values within the limits of normal. On the other hand, in cases in which the chorea arose at the same time as, or in direct connection with, polyarthritis, endocarditis, or pericarditis, microsedimentation was increased, and the sedimentation curve seemed to be influenced by the other diseases. It was upon

¹Landau, A.: *Am. J. Dis. Child.*, 45: 691, 1933.

this finding that Landau based his agreement with Vollenberg's hypothesis of chorea as a metarheumatic disease, or as an intoxication of the cerebral cortex.

The blood sedimentation rate has been used extensively in following patients with pulmonary tuberculosis as a gauge of activity and response to therapy. In tuberculosis of the bronchial lymph nodes in children during periods of activity the blood sedimentation rate is elevated. Westergren states that blood sedimentation in bronchial lymph node tuberculosis in children after one hour is 50 mm. during the period of activity. It then sinks rapidly and after two months is around 10 mm. Dehoff found that in active tuberculosis of the hilus the blood sedimentation rate with the Linzenmeier tube was such that 280 minutes were required for the blood plasma to reach the mark 18 mm. Rókay, using the Westergren method, found the blood sedimentation values as given in Table 82, in cases of hilar gland tuberculosis.

Blood sedimentation in children with polycythemia is very high whereas in adults it tends to be low. According to Schönberger,¹ in myxedema the blood sedimentation rate is enormously accelerated, but glandular therapy may return it to normal very rapidly.

¹Schönberger: Ztschr. f. Kinderh. 38: 688, 1924.

In arthritis in adults, the sedimentation rate is definitely increased in the infectious or atrophic, rheumatic and rheumatoid type, and is normal in the noninfectious, or hypertrophic, degenerative, osteoarthritic type.

In psychoneurotic cases with unusual symptoms, in which no organic lesion may be found, repeatedly normal sedimentation rates aid in excluding organic disease.

The sedimentation rate is retarded in asthma, hay fever, and urticaria and other allergic states.

In pertussis, with the sedimentation rate normal and a high lymphocyte count, we have an unusual condition, namely, a normal rate in a febrile disease. In all other febrile diseases, it is apparently increased.

It must be borne in mind that the sedimentation rate and the hemogram are both independent of the fever curve. They both may be negative or positive with and without fever, but they parallel temperature reactions only in the climax of severe inflammatory processes. Expressed in other terms, the hemogram reaction is exceedingly useful in acute infections, while the sedimentation rate is important in the more chronic conditions.

The sedimentation rate has been found useful in following the course of coronary occlusion in adults. The rate tends to be high early and increases as the myocardial infarction spreads. Decline in the rate occurs when the process of infarction ceases. In other cardiac diseases in adults not associated with infarction, the sedimentation rate tends to be normal.

In summary, the sedimentation rate finds a wide field of clinical applicability. It is not a specific diagnostic test, although it may influence differential diagnosis. Its greatest usefulness is in following the course of diseases known to have increased sedimentation rates. As an adjunct to its reflection of the progress of such diseases, the sedimentation rate acts as a yardstick of the efficacy of treatment. Although single determinations have value, *changes* in multiple determinations in a given case are of even greater significance in the evaluation of a patient.

Methodology in sedimentation rate determinations deserves some comment. The various types of apparatus and the dissimilarity of reporting results attest to the interest manifested in this procedure. In general, we feel that the test has been made unnecessarily complicated, considering its clinical usefulness. Any method with one reading in an hour, giving the amount of settling of the erythrocytes, appears quite adequate. Those methods requiring graphs of various types appear to us as unnecessary refinements. We have included many of the methods in this text for historic interest rather than clinical value.

Greisheimer, Treloar, and Ryan² attempted to draw conclusions about the average relationship existing between the Cutler, the Linzenmeier, and the Westergren methods. They found that a sedimentation of one hour for normal subjects seems to be reasonably concordant for the three methods despite the wide differences in tube width, anticoagulant concentration, and length of fluid column, although the differences between the means for the three methods are significant statistically. The average sedimentation at one hour for women is approximately double that for men. They showed by tables the

²Greisheimer, E. M., Treloar, A. E., and Ryan, M.: *Am. J. M. Sc.* 187: 213, 1934.

various indices and differences between the three methods and attempted to establish some ratios between them. Their tables demonstrate that the regression lines for predicting the most likely value to be expected by any one test when that by another is known are of three distinct types. There is a rectilinear relationship between the Cutler index and the Linzenmeier index. The linear regression differences between Westergren index and Cutler or Linzenmeier index appear to be somewhat like saturation curves. It was impossible to fit this into a systematic scheme by any type of mathematical equation. The relationships between the various indices and Linzenmeier time values may be suitably portrayed by sections of hyperbolae. Individual tables have been given by them for each independent variable of clinical interest. The dispersals of individual cases about the lines of average relationship, although not studied in detail, are clearly greater than those ascribable to errors inherent in the technics. It is obvious that sedimentation measures for human blood are, in part, specific for the technic employed. It would be advantageous, therefore, to have a standardized method for blood sedimentation for clinical work but, as yet, this has not been done. We must, therefore, in estimating the importance of the sedimentation rate in any individual case be familiar with the sedimentation rate in such cases, the method used, and the normal value for that method.

Watkins¹ emphasized the fact that variations in the room temperature markedly affect the sedimentation rate. Sedimentation rate is retarded in a cooler room. Table 84 gives comparisons on stored blood and blood rechecked after 18 hours.

TABLE 84

CASE	ROOM TEMPERATURE		AFTER 18 HRS.		
	READING		AT 10° C.		
1	24 mm.	(1 hr.)	3 mm.	(2 hrs.)	5 mm. (3 hrs.) 9 mm.
2a	31 mm.		15 mm.		
3b	27 mm.		25 mm.		
4	24 mm.		17 mm.		
5c (25° C.)	12 mm.	(37° C.)	20 mm.		

a. Hemolytic anemia.

b. Pregnancy in latter months.

c. The variation between 25°C. and 37° C. in the sedimentation rate of erythrocytes is exactly 8 mm. There is a change from a normal or approximately normal to a definitely increased sedimentation rate of erythrocytes.

In carrying out blood sedimentation tests, either an electric light bulb or preferably the standard bacteriologic incubator can be used quite satisfactorily. Racks containing the blood can be placed near the lamp or in the incubator. A thermometer must be placed near the blood so that records of the temperature can be made quickly and accurately. Watkins preferred the small Cutler tube for this work because (1) the smaller tube affords less surface area exposed to the reducing of temperature; (2) smaller amounts of blood can be used; (3) it is less cumbersome in handling and placing in the incubator; and (4) it maintains constant temperature.

It is important to hold the blood near body temperature until the test can be recorded. Chilling the blood before making the test will definitely alter the final results.

The influence of anemia on the blood sedimentation rate has been studied by many hematologists. Certain authors have suggested a correction of the

¹Watkins, R. G.: Lab. Digest 10: 4, 1946.

sedimentation rate taking into consideration the number of erythrocytes, the blood volume, the corpuscular volume, the average diameter of the erythrocytes, or their hemoglobin content.

According to Adura,¹ the influence of the erythrocytes on the sedimentation rate, if present at all, is very small *in vivo*. Therefore, for actual practice, consideration of the erythrocytes is unnecessary. The essential factors in sedimentation of erythrocytes are the physicochemical and electric alterations of the plasma. Specific weight of the erythrocytes is not to be considered a major factor. Adura points out that the sedimentation rates differ greatly in cattle and horses, although the specific gravity is identical. Comparative studies made on hypochromic and hyperchromic erythrocytes showed that hemoglobin content does not materially influence the sedimentation rate. It can be shown, also, that the average diameter of the erythrocytes is of no significance in this respect. Adura pointed out that when erythrocytes from pregnant women or from patients with infectious diseases (accelerated sedimentation) were washed and then placed in the plasma of normal persons, a normal sedimentation rate was obtained. On the other hand, when the washed erythrocytes of healthy individuals were placed in plasma of pregnant women, the sedimentation rate was greatly accelerated.

We are in agreement with Adura that these experiments prove that the plasma is the regulating factor in blood sedimentation, and that correction of the sedimentation rate on the basis of factors concerning the erythrocytes may even diminish the value of the reaction, as thereby an extrinsic and inconstant factor is introduced which unnecessarily complicates the otherwise easy test.

The comments in the preceding two paragraphs have appeared in previous editions of this text. Wintrobe, who has been a strong advocate of correction of the sedimentation rate for anemia, now has abandoned such corrections as an unnecessary refinement of a crude test. Note of his present stand under the Wintrobe technic has been made, and the correction chart which formerly accompanied his technic has been eliminated. Meyers and associates² tried to devise some means of adjusting all sedimentation rates to a standard cell volume and as a result of their studies cast "serious doubt on the validity of any such correction charts."²

HEMATOLOGY OF INFANTS AND CHILDREN

Since blood pictures in infants and children normally differ somewhat from those in adults, we shall give briefly the salient differences so that proper interpretation of findings may be made.

At birth the number of white cells is very high, around 30,000, declining to normal after the first week. It is also interesting to note that there is a left shift during the first week of life. The count of the blood platelets is also variable during the first week, sometimes reaching very high proportions.

The percentage of hemoglobin in blood at birth is very high, figures as high as 130 per cent having been obtained. Hemoglobin falls soon after birth, reaching normal around the end of the first week.

¹Adura, Ac.: *Merrame-Anais paulistas de medicina e cirurgia* 42: 135, 1941; *Internat. Med. Digest* 39: 6, 1941. W. F. Prior Co.

²Meyers, A. J., and others, *loc. cit.*

The number of red cells is very high at birth, beginning to fall on the third day after birth.

At birth, the presence of nucleated red cells in the film has no pathologic significance. The same is true of the great prevalence of reticulocytes and polychromatic cells. Anisocytosis is common and not pathologic.

The newborn child shows in its blood the last remnants of the nuclear structures of embryonal life. They persist up to the third or fourth day. The leukocytic system develops in the same way, phylogenetic lymphoid elements and genuine lymphocytes constituting the predominant element, followed by the appearance of lympholeukocytic and granulocytic elements. Naegeli, Schridde, and others maintain that lymphocytes develop embryonally very late, then steadily increase together with a general development of granulocytes and erythrocytes in the liver, spleen, kidneys, vascular system, and interstitial tissue. The bone marrow of the baby contains many more cells than that of the adult. This bone marrow is transformed into the fat marrow of the long bones, remaining hematopoietic, however, in the short bones. The

8 days	10,700	28.6%	63.2%	1.2%	6.2%	0.8%	—

*Baar and Stransky: Die klinische Hematologie des Kindesalters, p. 6, Franz Deuticke, Wien, 1928.

ratio between white blood corpuscles and erythrocytes is very much higher in the later embryonal months than in the adult. We know that there is a greater lability of the bone marrow of the child than of the adult. This is true of their lymphatic systems as well. There are far more unusual cells in the blood—plasma cells and atypical lymphocytes. It is, therefore, necessary in all cases to make intensive detailed studies of blood pictures of children in order to correlate them properly with clinical facts.

One must divide these young subjects into three groups in order to get a proper estimation of hematologic data: newborn babies; nursing infants; and infants from one to six years of age. The average adult blood picture is not reached before the sixth year, but even then, and sometimes later, lymphatic reactions are produced much more easily than in the adult and wide fluctuations are commonly seen. In general, the blood picture at birth is markedly neutrophilic and shows a great shift to the left. Physiologic myelocytes and juveniles have been seen at this time under perfectly normal conditions. The neutrophilia with marked shift has been explained by Zange-meister and Missl as the result of the influence of maternal blood or, as Arneth says, it represents a "pathologic" leukocytosis of the birth process. It is very probable that the accommodation of the body to the new circula-

tion and respiration irritates the residue of embryonal blood forms and liberates them into the blood stream. Lymphocytes increase rapidly in the relative picture.

The blood pictures of prematurely born babies exhibit greater abnormalities than those of normally born children; that is to say, their blood pictures may closely approximate the embryonal blood picture. Prematurely born children at first show a high leukocytosis and neutrophilia. This recedes, together with the marked nuclear shift.

The Blood Picture of Nursing Infants

The blood picture of the nursling remains constant in the first year and up to the middle of the second; at this time, it begins to change gradually into an appearance like that of the blood of the adult, finally attaining this adult appearance about the sixth year. There is still a high *lymphocytosis* together with a slight nuclear shift under perfectly normal conditions. The number of neutrophiles in the nursing child is about 25 to 30 per cent and the lymphocytes are from 42.5 to 90.5 per cent, according to Hofmann and Welker. Gundobin considers this the average for nurslings: neutrophiles 34.6; lymphocytes 59.0; and monocytes 6.4.

Zibordi¹ reports the following investigation of breast-fed children, mixed-breast-and-artificial, and artificially fed children with the Arneth classification. In the first group are designated the breast-fed children up to the tenth month; in the second group, children on a mixed diet; and in the third group, artificially fed children.

Morphology of the Blood in Infancy

There is an extreme lability of the blood-forming apparatus in early infancy; that is to say, it is much more sensitive to irritation than that of the older individual.

14-15 years	56.45%	28.22%	8.87%	0.6 %	5.86%

Many authorities have noted the high percentage of hemoglobin and increase of cell count at birth. These figures rapidly fall after the first few days. Perlin noted a drop in hemoglobin after the fourth day with a gradual decrease, reaching its minimum at the end of the first year, namely, 58 to 78 per cent. From the second year on, it begins to rise, up to the fifteenth or sixteenth year of life.

The count of the red cells drops soon after birth. Toward the end of the first year, it is at its lowest point; namely, 4,200,000, when the count begins to rise up to the end of the fourth year.

Williamson and Appleton¹ give the figures shown in Table 87.

The number of red and white cells as given by Carstanjen² is shown in Table 88.

Karnicki gives the qualitative blood picture shown in Table 89.

There is a difference in the hemoglobin content and the number of red cells in breast-fed children and artificially fed children, about 10 per cent, according to Zibordi.

One must be careful in infancy cases in drawing conclusions from the shift of the neutrophils for the reason that 1.5 per cent juveniles and 18 per cent stabs as well as an occasional myelocyte have been found in healthy infants. This is due to the remarkable lability of the hematopoietic apparatus in infancy. *The hemogram of Schilling is useful in infancy but not from a single examination. Conclusions must be drawn only from repeated examinations.*

The number of blood platelets in infancy varies greatly. The average count is between 200,000 and 300,000. McClanahan and Mitarbeiter³ in a report on 68 blood examinations in infancy give the figures shown in Table 90 on blood platelets.

The hemoglobin content of the blood of children from 1 to 10 years is seen in Table 91.

The qualitative blood picture according to Carstanjen from the first to the fifteenth year is shown in Table 92.

Sedimentation phenomenon of the red cells in infancy is different from that of adults. In the Linzenmeier test tube in adult females, sedimentation drops to 18 mm. in 800 to 1,000 minutes, in males in 1,200 to 1,400 minutes. In newborn babies, the sedimentation rate of 18 mm. occurs in from 6 to 7 hours, but after the first month, the rate is 90 minutes; and in diseases such as syphilis and tuberculosis it is even faster. (See pages 959 ff.)

Blood Picture of Prematurely Born Children

The blood of prematurely born children offers an interesting study. In the first two weeks, the average percentage of hemoglobin is 105; in the third week, 93; and in the fourth week, 68; in the second month, 55; in the third month, 47; in the fourth month, 50; and in the fifth month, 52. The number of red cells begins to decrease after the second month, reaching its minimum in the third month and attaining a normal figure in the sixth month. There

¹Quoted by Baar and Stransky: l. c.

²Carstanjen: Jahrb. f. Kinderhk. 52: 215, 333, 648, 1900.

³Arch. Pediat. 33: 757, 1916.

is a leukopenia in all these babies up to the sixth month. Lichtenstein regards the anemia of prematurely born babies as physiologic.

Frankenstein and Stecher, in a study of the blood picture of prematurely born babies for the first twelve weeks of life, show a lymphocyte average of 72 per cent in the second week, and 82 per cent in the fourth week, which drops later to 72 per cent. Segmented forms in the first five days are between 20 and 28 per cent, rising to 35 per cent, dropping to 26 per cent on the eighth day and to 10 per cent in the fourth week. The "stabs" decrease in the first week from 12 to 4 per cent. Juvenile forms in this period show 0.5 to 1 per cent.

Blood Picture of Children from One to Six Years

These subjects show a gradual approach of the nursling's blood picture to that of the adult. Note Table 92, page 978, of Carstanjen, showing the changes from the first to the fifteenth year. The decrease in lymphocytes begins definitely about the end of the second year.

Changes in the Leukocytic Picture Under Physiologic and Pathologic Influences in Infancy

Virchow first called attention to digestion leukocytosis. He noted an enlargement of the mesenteric lymph glands after a meal, together with an increase in white cells in the circulating blood. Gregor in 1898 failed to confirm this phenomenon in healthy infants. In eleven cases he found from three to five hours after a meal some degree of leukocytosis, but in six cases he noted a leukopenia. In general, digestion leukocytosis is not constant in infancy. On the contrary, there is more likely to be a leukopenia. Schiff and Stransky claim that in healthy, as well as in artificially nourished infants, whether the lymph is disturbed or not after a milk meal, there follows a leukopenia.

No reliable data are at hand as to the shift in the hemogram as a result of the digestion of food.

Wernstedt¹ found the leukocyte count in infants lower while asleep than it was when they were awake. There is a lymphocytosis described as a result of efforts in crying, but this disappears after thirty minutes of rest. It is probable that the lymphocytes in crying infants, and in whooping cough cases, come from the spleen and the thoracic duct. This exercise leukocytosis was first described by Grawitz in 1910.

In intoxications of infants, not due to infectious diseases, the total white cell count may be elevated up to 20,000. There is a slight shift to the left in such cases. In intestinal decomposition, there is a slight shift, and in extreme cases of marasmus, there is a definite left shift. In general, however, a left shift speaks for an infection. In acute toxicosis, there is a leukocytosis.

The significance of eosinophilia in infancy has been the subject of much discussion. In general, we find an eosinophilia in all cases of exudative diathesis. This is particularly true of eczemas of infants, but it is believed that eosinophilia is not due to the local process, but to the underlying cause of

¹Monatschr. f. Kinderh. 9: 343, 1911.

eczema. Figures as high as 65 per cent eosinophiles have been noted. Eosinophiles in all acute dermatoses are decreased, and they are increased in all chronic cases, particularly in eczema. In erythrodermia desquamativa, the leukocyte count is elevated to 12,000 with a high-grade anemia and with a count of eosinophiles between 1 and 6 per cent.

Erythroblastosis Fetalis (Icterus Gravis Neonatorum)

This is often a fatal condition which has been the subject of considerable investigation. It is usually due to an intra-group hemolytic reaction incident to the mating of an Rh-positive father with an Rh-negative mother. (See pages 1026 ff., 1031 to 1055.) These cases must be clearly distinguished from icterus of the newborn due to congenital syphilis. It has been well described clinically by Buhler, Seely, and McCormick,¹ who reported on this disease in dizygotic twins. The clinical manifestations and their development will depend on whether the predominate pattern be evidenced by edema or icterus or simply by the blood findings of anemia and increased number of nucleated red blood cells. Hydrops, when associated with either of the other two, is fatal, and the infant is either stillborn or dies immediately after birth. If the jaundice predominates, it may be present at birth or develop shortly thereafter. If present at birth, the vernix may be a golden yellow and the placenta and the amniotic fluid may have an icteric tint. Potter and Adair² point out that neither the anemia nor increased nucleated red blood cells alone are sufficient for a diagnosis of erythroblastosis fetalis and many cases so diagnosed with subsequent recovery are probably erroneous. Buhler et al. record the symptoms in infants as follows: lethargy and exhaustion; symptoms may develop rapidly depending upon the rate of blood destruction; petechial hemorrhages may appear; heart is often enlarged; rapid and weak pulse; no fever usually; liver and spleen are enlarged; and, due to deposition of blood pigment in localized areas of the brain, a syndrome called kernicterus may develop which may quickly cause death. McKinley³ records the early symptoms of kernicterus as convulsions, neck retraction, respiratory paralysis, and drowsiness.

Danis and Anderson⁴ consider the syndromes, congenital hydrops, erythroblastosis fetalis, icterus gravis, and anemia of the newborn, as one condition; namely, a condition known as icterus gravis neonatorum. Their studies on three cases with a favorable outcome and four cases studied by autopsy examinations are quite revealing. Knowing that liver dysfunction was undoubtedly part and parcel of this disease, they studied the faulty fat metabolism in these cases. It was Klemperer⁵ who suggested faulty fat metabolism in this condition, by demonstrating the presence of fatty infiltration with degeneration and necrosis in the cases he studied. The present writers found in the sections of livers of babies dying of this disease fatty infiltration as well as the hemopoietic activity usually found. Griffith⁶ noted a similar fatty change in the liver in choline deficient rats.

⁶Griffith, W. H.: *Editorial Reviews* 22: No. 3, Nutrition, Sept. 10, 1941.

It is interesting to note that the prothrombin time in icterus gravis remains high throughout its course on ordinary treatment. This high prothrombin time returned to normal in the three cases that recovered without the complication of kernicterus but this rate of recovery was accelerated by the administration of choline. The **use of choline** came about as follows: the relation of fat metabolism to liver function is uncertain. When neutral fats are absorbed, fat metabolism is carried on in the liver through phospholipid mediation. In the absence of adequate choline, the intermediary catalysis of fatty acids by the liver phospholipid is markedly inhibited. Neutral fat then accumulates in the liver in immense proportions, arising from normal 3 per cent to 27 to 40 per cent. If one feeds cholesterol to rats and guinea pigs a similar accumulation occurs aggravated by choline lack. These writers state that choline is effective through its labile methyl content. It is probable that in the presence of immense fat deposits of triglyceride, the liver cell is functioning under a burden of fat and may deviate from its normal efficiency and metabolism. They therefore added choline to the diet, consisting of Mead Johnson's Olac, thus supplying a form of fat easily absorbable with less possibility of forming cholesterol than butter fat and containing labile methyl through the casein content. This was begun after multiple blood transfusions brought the anemia under control but where the jaundice and liver dysfunction were both at a standstill. In other words, they secured evidence of the rationale of this method of treatment, because they started some time after the effects of the blood transfusions had become manifest and the recovery, which was accelerated, was plainly not due to the transfusions. Obviously, this type of vegetable fat, with labile methyl-containing choline chloride and labile methyl-containing casein, seems indicated in the presence of faulty fat metabolism such as occurs in icterus gravis neonatorum (see pages 1075 ff., exsanguination transfusion).

Laboratory findings,²⁻⁶ are those of a macrocytic hyperchromic, hypochromic anemia associated with a hemolytic type of jaundice. There is an increase in the nucleated red cells. Hemoglobin varies from 25 per cent to 60 per cent. The red cell count is from 1,000,000 to 3,000,000. Reticulocytes are increased from 15 to 20 per cent. Poikilocytosis and anisocytosis are present. Leukocytosis is often marked with an increase in the young white forms. There have been reports of as many as 260,000 white blood cells.* Platelet counts are inconstant and fragility tests variable. Bleeding time is often prolonged; the coagulation time is not affected. The urine contains bilirubin. The stools may be acholic, but more often are not.

Pathologic features are a universal hydrops, with edematous tissues, ascites, hydrothorax, and hydropericardium. Icterus, when present, is the outstanding finding.

*We have not found leukocyte counts of any such proportions. There are many nucleated red blood cells present, the nuclei of which do not dissolve in acetic acid. The white counts should be made under high power, according to the directions on page 577. (R.B.H.G.)

⁶Sanford, H. N.: *Erythroblastosis Fetalis*, *Practice of Pediatrics* (Brennemann), Hagerstown, W. B. Prior Co., vol. 3, pp. 16-22.

Microscopically, the tissues show extramedullary hemopoiesis and blood destruction with islands of erythropoiesis occurring in the liver, spleen, adrenals, kidneys, and occasionally, in other organs. The bone marrow is hyperplastic. Bile deposition and cell destruction are noted in the nuclear areas of the brain. The placental pathology is characteristic, namely, increase in size, grayish or icteric in color with friable, edematous villi. Microscopically the villi are enlarged and the vessels are filled with nucleated red cells.

Those infants exhibiting universal hydrops are either stillborn or die shortly after birth. Those with icterus at birth, or developing icterus within a few hours, carry a worse prognosis than those cases developing jaundice later. In all its forms, the disease shows a high mortality rate.

It is sometimes difficult to make a differential diagnosis between erythroblastosis fetalis and congenital syphilis. Osteochondritis, as shown by roentgenograms of the long bones, may help, also positive serologic findings and history of laboratory evidence of a syphilitic infection in the mother. Hemorrhagic disease of the newborn, accompanied by jaundice, is to be ruled out. Prothrombin determinations, predominate hemorrhagic tendencies, and response to specific therapy help to eliminate this diagnosis.

A case reported by the author¹ is a typical example of this intragroup isoimmunization leading to erythroblastosis fetalis. (See Plates XXVII and XXVIII.)

A pregnant woman was delivered of a baby with erythroblastosis fetalis, which was recognized by the severe icterus and the blood picture. The child lived but a few days, then died. Autopsy showed a very large liver and spleen. **Bone marrow** studies of the baby showed the following picture:

Megakaryocytes	0.25	
Myeloblast	2.50

For every 100 leukocytes, there were

20 Polychromatic normoblasts
 3 Polychromatic macroblasts
 5 Polychromatic megaloblasts
 0.25 Erythrogonia.

Many cells highly vacuolated and atypical.

Toxic granules of neutrophiles.

Many fragmentary nuclear structures.

2 Giant segmented neutrophiles.

Macrocytes present.

Anisocytosis.

Marked, intensely blue, polychromasia.

Karyogenic metachromasia.

The father's blood was Rh positive: the baby's blood was Rh positive: the mother's blood was Rh negative. The mother's blood when tested failed to show anti-Rh agglutinins in the blood serum. This was the second pregnancy in this patient that resulted in erythroblastosis fetalis: first two years prior to this recent event. It is interesting to note that her first pregnancy, six years ago, resulted in a healthy child. This observation has been made by Levine; namely, that isoimmunization to the extent of always producing hemolytic changes or icterus gravis in the fetus does not occur with every pregnancy, but that usually the first child is spared.

Agglutinins were not found in the mother in this case because it goes back to 1942. Since then improved technics, involving tests for univalent or blocking antibodies, would reveal such agglutinins in the mother.

Congenital Leukemia

A number of cases of congenital leukemia have been noted in the literature. They are usually of the acute type; they may be myelocytic or lymphocytic.

Congenital Malaria

Congenital malaria is looked for and expected in malarial districts. The diagnosis is made by finding the characteristic blood picture of malaria including plasmodia.

Congenital Syphilis

In this disease, there is no characteristic blood picture. We see a very severe anemia, hemorrhagic diathesis, and blood serology, which are sufficient to make the diagnosis.

Congenital Anemia

A number of cases of so-called congenital anemia have been reported. These show anisocytosis, poikilocytosis, and polychromasia.

It is claimed that there are two primary anemias. The etiology is based upon a toxic irritation or a primary weakness in the hematopoietic apparatus. It is interesting to note that anemia of the mother is usually not carried over to the child, not even in severe cases of pernicious anemia. This applies both to the pernicious-like anemia, which has been called a pernicious-pregnancy-anemia, and true pernicious anemia. It is also true that maternal leukemia is not carried over to the child.

Anemias of Infancy and Childhood

Anemia is very common in these young subjects. Attention has already been called to the discrepancies in the figures of hemoglobin and red cells between infancy and adult ages. The physiologic anemia of premature babies has already been considered. A classification of anemias in children is more difficult than it is in adults. The following groups may be considered:

1. Anemia perniciosa of Biermer.
2. The "aplastic anemia" of Ehrlich, also called "hemolytic anemia" of Türk, or the "aregenerative anemia" of Pappenheim, or the "aleukia hemorrhagica" of Frank.
3. Progressive postinfectious anemia.
4. Congenital and inherited hemolytic icterus.

Whether true pernicious anemia occurs in children is debatable. Most of the cases that have been described with pernicious anemic blood pictures are connected with *Diphyllobothrium* infestation.

Anemia Pseudoleukemica Infantum of von Jaksch

This is a special disease of children between the ages of six months and two years. It is an anemia of moderate degree with a high-grade dystrophy and enlargement of the spleen. Most of these children are rachitic. The following hematologic changes are seen:

1. Definite decrease in cell volume.
2. Definite decrease in hemoglobin content.
3. Marked decline in number of red cells.
4. High-grade progressive increase in leukocytes.
5. Changes in size and morphology of the red cells together with the presence of many nucleated red cells. There are many karyokinetic figures.
6. Relative quantities of white cells to red cells, as in the proportion of 1:100.

Baar and Stransky¹ describe a typical case as follows:

E. N., six months old, twin, normal birth, weighed 1,600 gm. at birth. The twin sister weighed 1,850 gm. Breast fed for two months, then fed mother's and cow's milk, equal parts. For four weeks had daily 800 or 900 gm.—2/3 milk and vegetables twice daily.

¹Baar, H., and Stransky, E.: *Klinische Hämatologie des Kindesalters*, Franz Deuticke, Leipzig und Wien, 1928, p. 86.

Patient affected with grippe for last fourteen days, with fever four days at 39.5° C.; since then fever-free. Patient since this time showed great pallor and poor appetite. Stool normal. Mother has a bronchial catarrh; father healthy. Twin sister healthy, not pale. Status praesens: Small, weak, poorly nourished, pale child. Skin high-grade anemic with a yellow color tone. Visible mucosae pale. Lobes of the ears by transmitted light almost colorless. Few ecchymoses of the skin. Definite craniotabes rachitica, rachitic rosary. Thorax weak. No lymph gland enlargement. Chvostek negative. Throat mucosa pale. Lung findings negative. Heart findings negative. Abdomen distended. Spleen reaches to the umbilicus. Splenic tumor extends four fingerbreadths below the left costal border. Liver four fingerbreadths below the right costal border. Urine shows increased urobilinogen. Blood findings: hemoglobin (Sahli) 30 per cent; erythrocytes 2,060,000; color index 0.75; leukocytes 24,100; blood platelets 40,000; stabs 1.8; segments 21; lymphocytes 72.4; monocytes 2.8; eosinophiles 1.2; basophiles 0.2; neutrophilic myelocytes 0.2; myeloblasts 0.2; plasma cells 0.2. Red cells show anisocytosis, poikilocytosis, and polychromasia.

In general, anemia infantum pseudoleukemica is a symptom complex with anemia, erythroblastosis, myelogenous reaction, and a splenic tumor.

Erythroblastic Anemia or Cooley's Anemia

Under this title Cooley and Lee² reported five cases which showed symptoms similar to the von Jaksch disease just described. Cooley, Witwer, and Lee³ later reported two more similar cases. All these cases showed severe secondary anemia, enlarged spleens, leukocytosis of varying degrees, many normoblasts, and normal or increased fragility to salt solutions. Others have reported similar cases.⁴ In this connection, Cooley believes that von Jaksch probably erred in stating that many of these cases recovered, due no doubt to the fact that in the group originally classified by von Jaksch, there were many cases of ordinary secondary anemia which did not properly belong to this group. At the same time, von Jaksch, in his original paper in 1889, did not emphasize the occurrence of nucleated reds nor the appearance of immature white cells in these cases.

For information concerning the disease, now spoken of as "thalassemia," and for the blood picture, refer to page 731.

Chlorosis

The question has been raised—does a child ever have a true chlorosis, or is it a chlorotic-like disease that we see in these young subjects? The definition of chlorosis, as given by von Noorden follows:

1. A disease of female puberty with tendency to recurrence.
2. Cardinal symptom of this disease is anemia, decline in hemoglobin, and number of red cells. As a result of the anemia, we have the various symptoms of the disease.
3. The disease develops spontaneously without apparently any existing cause.

Baty, Blackfan, and Diamond: Am. J. Dis. Child. 43: 667, 1932.

Crawford and Williamson: Am. J. Dis. Child. 46: 565, 1933.

4. The disease is only a disturbance of the nutritional state of the blood without any disturbances in the general nutritional state of the individual affected.

It is generally conceded that true chlorosis does not occur in children, but that we have at times a chlorotic-like anemia. Baar has described a pseudochlorosis infantum characterized by lack of iron in the blood stream.

Anemia of Scurvy

In scurvy, we find a characteristic bone marrow disturbance which was well described by Senator. Cases of scurvy anemia have been fully described in the literature.

There is an anemia which is seen in cases of dystrophia avitaminosa. These cases have been recorded in connection with so-called "goat-milk dystrophia" and "goat-milk anemia."

Alimentary Anemias

Alimentary anemias in pediatrics may be divided into the two following groups:

1. Pseudochlorosis infantum or infantile lack of iron, or infantile iron-poor anemia.
2. Alimentary infectious anemia.

Infectious and Postinfectious Anemia

These cases follow such infections as congenital syphilis, sepsis, and malaria. In tropical countries, it is very often difficult to distinguish between chronic malaria in children and leishmaniasis infantum. In chronic malaria, there is an early appearance of fever, gastrointestinal disturbance, spleen and liver edema, and anemia with pallor. In leishmaniasis there is a late development of these symptoms, followed by a late fever and gastrointestinal symptoms. In chronic malaria, there is swelling of the liver and spleen with a sensitiveness of these organs particularly to pressure in the neighborhood of the phrenic nerve. In leishmaniasis, there is swelling of the liver and spleen but no sensitiveness. In chronic malaria, there are gastrointestinal disturbances more often with constipation than diarrhea, whereas in leishmaniasis, gastrointestinal symptoms occur but more often with diarrhea than constipation. The edema in chronic malaria has certain definite localizations, such as the face or the lower extremities, whereas in leishmaniasis, the edema is seldom in the face and more often on the lower extremities. In leishmaniasis the blood shows an oligemia; erythroblasts are rare. White cells are decreased. There is usually a relative lymphocytosis. Resistance of the red cells to hemolysis in hypotonic salt solution is lowered. Parasites may be found in the blood very rarely but can be found in splenic puncture.

Hematoxic Anemia

Anemias due to poisons such as lead, potassium chlorate, pyrogallol, etc., are not different in children than they are in adults. There are many cases

of lead anemia seen in infants and children. It is interesting to note that a symptom of lead poisoning in infants is a convulsion.

Lead anemia has already been described. (See Hematology of Lead Poisoning.) A very important symptom of lead poisoning in children is the deposit of lead in the ends of the growing bones which can easily be determined by roentgenologic examinations.

Anemia Due to Intestinal Parasites

Severe anemias in children due to intestinal parasites are very common. These are seen in connection with infestation with *Diphyllobotrium latum* and *Taenia*. Theodor, Cima, Naegeli, and others have repeatedly called attention to anemias due to infestations due to *Trichuris trichiura*. Cima, Cozzolino, Ashford and others have described anemias due to *Ancylostoma duodenale*; and those due to *Schistosoma haematobium* have been described by Kautzky-Bey. Stäubli, van Cott, and others have described the anemias due to trichinosis. Kautzky-Bey claims that *Schistosoma haematobium* and not *Ancylostoma duodenale* is the causative agent of the so-called "Egyptian anemia" in children. "Egyptian anemia" is characterized by a disturbed relationship between the hemoglobin content and the number of red cells and by the presence of oligochromemia and a marked eosinophilia. In trichinosis in children there is at first a polycythemia and later a slight hypochromic anemia. *Ascaris* and *Enterobius* (*Oxyuris*) infestations do not often produce anemizing symptoms.

Constitutional Anemia

By "constitutional anemias" is meant those due to some cause other than poisoning or infections. Many of these cases are due to disturbances of the glands of internal secretion. Some are due to a let-down in the physiologic activity of the hematopoietic organs. In this latter type are seen anemias in connection with stigmata of degeneration and hydrocephalic children.

The blood picture seen in these cases is anemia without any indications of a regenerative tendency. To these constitutional anemias belong such diseases as erythrodermia desquamativa and also sickle cell anemia. The anemia connected with internal glandular secretory function is seen particularly in myxedema. Here is seen an oligocythemia, oligochromemia, relative lymphocytosis, leukopenia, and often an eosinophilia. "Kocher" blood picture is also characteristic in myxedema; namely, lymphocytosis and neutropenia.

Pernicious Anemia

True pernicious anemia is seldom if ever seen in children. Most cases are really "pernicious anemia blood pictures" due to infestations by worms. It is generally conceded that children are not disposed toward pernicious anemia.

Aplastic Anemia

Aplastic anemia was first described by Ehrlich in 1888. It has also been called hemorrhagic aleukia, panmyelophthisis of Frank, and aregenerative asthenic anemia of Pappenheim. For fuller details, see remarks under aplastic anemia in adults. Eppinger has divided this into two groups—acute and

chronic aplastic anemia. Typical cases of aplastic anemia are very rare in children. Most cases of so-called aplastic anemia in children are really cases of aleukemic leukemia with aplastic blood pictures.

Pseudoanemia (Sahli)

This has already been described. See page 765.

Acute Leukemia of Children

According to Fraenkel, this is a form of leukemia which begins suddenly and has a rapid termination. The first case reported was by Friedreich¹ in 1857. Up to 1889 Epstein had reported sixteen cases. Of the forty-five cases collected by Theodor² in 1897, nine occurred in children. A monograph of Benjamin and Sluka³ in 1907 reported thirty-six cases of acute leukemia in children from the age of 2 to 14 years.

These cases in children begin with fever, headache, pains in the legs, weakness, vomiting, and chills. They show a triad of symptoms, anemia, hemorrhagic diathesis, and ulcerative, gangrenous changes in the digestive tract, especially in the mouth. Other workers have described nodular changes in the skin as part of the acute leukemic process. Hemorrhagic diathesis, seen in the form of hemorrhages under the skin and visible mucosae and sometimes rectal hemorrhages, has been reported. Hemorrhage in the cerebrum may lead to hemiplegia. Subperiosteal hemorrhages occur. Swelling around the tibia has been reported. Changes in the central nervous system are seen in the form of polyneuritis.

The lymph glands are enlarged. Spleen is enlarged. The heart is enlarged; there is a small, accelerated pulse. Sometimes hemorrhagic nephritic symptoms are seen. Septic symptoms are noteworthy.

Blood picture in acute leukemia of children shows changes not only in the white cells but also in the erythrocytes and blood platelets. There is a severe progressive anemia combined with a subicterus. The red cell count may go below 1,000,000. The hemoglobin does not keep pace with the drop in red count, so that the color index is high. Megalocytes and megaloblasts may be seen, so that these cases have sometimes been mistaken for pernicious anemia. The number of white cells is so increased that the relativity of white cells to red cells is about 1:100. Wollstein and Bartlett⁴ refer to the aleukic stage of acute leukemia, where there is marked change in the differential picture, but not a great increase in the total number of white cells. In acute leukemia in children, we see large, nongranulated, single-nucleated cells. These juvenile lymphocytes in the case of acute lymphocytic leukemia are so definite that we can make a diagnosis upon their appearance. In the acute myelocytic leukemias, we see many mononucleated cells, the myelocytes of Ehrlich. There are also mononucleated eosinophilic leukocytes. There are many mitoses seen in the white cells. Resort must be had to the Graham oxydase stain to distinguish myeloid from lymphatic cells.

⁴Wollstein, M., and Bartlett, F.: *Am. J. Med. Sc.* 169: 819, 1925.

Chronic Leukemias of Children

Chronic leukemias of children are very common. They begin very insidiously with weakness, loss of appetite, and general disturbances in the nutritional status. The spleen enlarges slowly. The lymphatic glands enlarge later. Blood picture is very characteristic. Hemoglobin content and the number of red cells may be normal in the beginning but later declines. Later we see signs of chronic anemia, polychromasia, anisocytosis, poikilocytosis, and presence of normoblasts and megaloblasts.

At times, it is necessary to make a differential diagnosis between the blood picture of an infectious leukocytosis and that of a chronic leukemia in children. In both conditions the count of the leukocytes is increased, but eosinophiles and monocytes are low or absent in septic leukocytosis but are present in large amounts in chronic myelocytic leukemia.

Chronic lymphocytic leukemia in children has been described by a number of writers. A typical case of a 13-year-old boy is as follows:

Weakness, loss of appetite. Blood picture, 32 per cent hemoglobin, 1,570,000 red cells, and 463,000 white cells. In the film, 98 per cent lymphocytes, no myelocytes, very little anisocytosis or poikilocytosis, occasional normoblasts. Blood platelets are scarce.

Leukemias of Nurslings

Leukemias of nurslings are very rare. From the time of the discovery of this disease in 1845, by Virchow, up to 1914, only seventeen cases had been reported. Since then many have been reported.

Symptomatic Megalosplenism or Banti's Disease

The term "splenic anemia" does not refer to any specific disease; it is simply a term used to describe those cases with both enlargement of the spleen and anemia.

Splenic enlargement may occur in the following conditions: (1) in anemias—either a secondary regenerative form or in hemorrhagic anemia; (2) in the hemorrhagic diatheses, there is megalosplenism; (3) polycythemia; (4) in lymphatic leukemia or lymphogranuloma; (5) in myelocytic leukemia or in aleukic myeloses; (6) chronic infections, such as congenital syphilis, malaria, leishmaniasis, etc.; (7) in rickets in first year of life—later on, it disappears; (8) in acute infections, as typhoid fever, miliary tuberculosis, and septic infections; (9) Gaucher's disease and Niemann-Pick disease; (10) in localized splenic tuberculosis; (11) in Banti's disease where there is a fibroadenoma of the spleen, liver cirrhosis, and finally, anemia; (12) splenic tumors from circulatory disturbances such as cardiac stagnation in beginning heart failure, or beginning heart failure from valvular disease, or stagnation from acute or chronic thrombosis in the venae cavae, or through stagnation by reason of pericardial adhesions; (13) splenic tumor in liver cirrhosis.

Banti's disease is accompanied by enlargement of the spleen without any change in the lymphatic glands, followed by symptoms of simple anemia and by weakness, dyspnea, etc. Hemoglobin content may drop to 30 per cent. There follows a second period during which the liver enlarges without icterus and without ascites, but the splenomegalia remains. This lasts perhaps from

eight to thirteen months. The third period is accompanied by ascites and decrease in size of the liver. There is an atrophic cirrhosis in the liver. It occurs after hemorrhages or through the progressive liver atrophy. The number of red cells is not markedly decreased, but the color index is lower. Nucleated red cells are not seen. The lymphocytes are usually decreased. Histologic investigations of the organs in fatal cases of Banti's disease show a fibro-adenosis of the spleen, including the pulp as well as the follicles. In the second stage of the disease, there is a sclerotic condition of the intrahepatic veins, later a hypertrophy of the interstitial material. No siderosis is seen in the liver.

Blood Picture.—There is a marked and constant leukopenia, sometimes the white cells are down to 1,000. There is no change in the differential picture. As already noted, the anemia progresses with the advance in the disease. There is a low color index. There may be as few as 3,000,000 red cells with 40 per cent hemoglobin. Hemorrhages into the stomach are followed by further reduction in the red cells and hemoglobin percentage, together with the temporary posthemorrhagic leukocytosis. The anemia itself may be severe enough to be fatal. There is an increased resistance of the red cells.

Hemorrhagic Diseases of Children

Basically the mechanisms involved in hemorrhagic diseases in children are similar to those in hemorrhagic diseases in adults.

NORMAL BLOOD FINDINGS IN DOMESTICATED ANIMALS

The use of various animals for laboratory purposes requires some knowledge of the normal blood picture of these laboratory and domesticated animals.

Guinea Pigs.—

Guinea pigs have an average number of red cells of 5,250,000. The hemoglobin varies from 85 to 100 with an average of 94. The total number of leukocytes varies from 5,000 to 22,000 with an average of 11,000 to 12,000. Guinea pigs have an average of 350,000 blood platelets per cubic millimeter.

Rabbits.—

In rabbits, the number of red cells varies from 5 to 8 millions with an average of 6 millions. Average hemoglobin value is 96. The number of leukocytes ranges from 8,000 to 13,000 with an average of 11,000. The differential picture is lymphocytes, 45-55; monocytes, 2-8; polymorphonuclears, 40-50; eosinophiles, 0.5-1 and basophiles, 4-8. We have noted an average reticulocyte count of 4 to 6 per cent.

Cats.—

Total number of red cells is about 6 millions. Goodall¹ found the normal to vary from 7.28 to 8.6 millions with an average of 8 millions. There are 7,000 to 19,000 leukocytes with an average of 13,300. Goodall found higher numbers of leukocytes. The differential picture is monocytes, 37; neutrophils, 54; eosinophiles, 9; and mast cells (basophiles), 1.0.

¹Goodall, A.: J. Path. & Bact. 14: 195, 1910.

Dogs.—

Red cells range from 5 to 8 millions with an average of about 6 millions. Hemoglobin values vary from 55 to 104, with an average of 90. Different investigators have reported different quantities of leukocytes in dogs. Six thousand to 12,000 with an average of about 8,000 seems to be the normal for adult dogs. The differential picture is lymphocytes, 11-29, average 20; monocytes, 3-10, average 6; neutrophiles, 60-76, average 68; eosinophiles, 1-10.5, average 6; with basophiles very rarely found.

Goats.—

Red cells are 9 to 10 millions per cubic millimeter in amount. Leukocytes are around 10,000 per cubic millimeter.

Sheep.—

Average number of red cells is 8 millions and of leukocytes is 8,000. Amount of hemoglobin varies from 47 to 63 per cent. The percentage of white cells in the differential picture in sheep is lymphocytes, 40 to 60; monocytes, 3 to 11; neutrophiles, 30-55; eosinophiles, 0.2 to 0.8; basophiles, 0 to 2.

Cows.—

Red cells vary from 5 to 8 millions, with an average hemoglobin range of 45 to 85. Normal number of leukocytes is 5,000 to 10,000. Differential picture, according to Dimock and Thompson,² is lymphocytes, 54.2%; monocytes, 1.4; neutrophiles, 30.5; eosinophiles, 13.15; basophiles 0.59.

Horses.—

Normal number of red cells for stallions is from 7 to 10 millions, with an average of 8 millions; for geldings 5½ to 9 millions with an average of 7½ to 8 millions; for mares, 5½ to 7½ millions with an average of 6½ to 7 millions. The hemoglobin varies from 85 to 100. Leukocytes vary from 5,000 to 10,000, with an average of 8,000. The differential picture is lymphocytes, 34 to 38; neutrophiles, 60 to 65; eosinophiles, 1 to 2.

Swine.—

Normal count of red cells is about 8 millions, slightly less for young pigs. Hemoglobin values are around 85. Leukocyte counts are 19,000 with more than 50 per cent of them lymphocytes. The differential picture of swine shows lymphocytes, 56.4; neutrophiles, 38; eosinophiles 5.13.

CHAPTER V

BLOOD GROUPS AND TRANSFUSION*

The first record of a blood transfusion is referred to in classical literature: Medea attempted to rejuvenate old Anchises by removing blood from his cervical vessels and replacing it with juvenile blood (Ovid). Obviously no genuine blood transfusion could have been performed prior to the discovery of the circulation of blood. Thomas Clark and Henshaw, soon after the discovery of the circulation of blood by William Harvey in 1616, began to make animal experiments on blood transfusion. Denys and Emmerez of Paris in 1667 made a direct transfusion of the blood from the carotid artery of a sheep into the cubital vein of a human patient, and good results followed. Others repeated this, but disastrous results occurred in some cases, so that it was abandoned. During the past century, blood transfusion was revived.

Owing to the fact, however, that severe reactions and death followed the transfusion of incompatible bloods, the procedure was practically abandoned for many years. It was revived only when methods were discovered for determination of the compatibility of human bloods. At the present time, methods of blood grouping and blood matching have eliminated many of the dangers incident to transfusion. It is now known that in most instances the unfavorable reactions were due either to hemolysis or to agglutination of either the donor's or recipient's blood cells or to both.

BLOOD GROUPS

Landsteiner¹ established the basis for present methods for determination of compatibility or incompatibility of bloods for transfusion. He discovered that all human beings can be divided into three distinct groups. He showed that the identity of each group depended upon the presence in the red blood cells of isoagglutinogens. He called these groups A, B, and C (not O). Group C was later called "O." A fourth group was discovered by von Decastello and Sturli.² This was the AB group. It was found that in the case of the group A, the serum reacted upon the corpuscles of group B, causing agglutination, but the serum of group A did not react upon the corpuscles of group A. The corpuscles of group A, in turn, were agglutinated or reacted upon by the serum of group B, but the serum of group B did not react upon the corpuscles of group B. It is obvious, therefore, that normally the corpuscles are apparently not sensitive to their own sera.

*We are indebted to Dr. Lester J. Unger, Director of the Blood and Plasma Bank, New York University-Bellevue Medical Center, New York City, N. Y., for his kind assistance in the revision of this chapter. Besides giving us the benefit of his advice and suggestions, Dr. Unger permitted my assistant, Mrs. Addine G. Erskine, to work in his laboratories to obtain first-hand knowledge of his technics so that they could be given here. It is our belief that this chapter, as now rewritten with the assistance of Dr. Unger, is the most complete treatise on this subject yet to appear in any textbook.

We also wish to thank Dr. Alexander S. Wiener, Brooklyn, N. Y., for having kindly read the entire manuscript.

¹Landsteiner, K.: *Wien. klin. Wchnschr.* 14: 1132, 1901.

²Münch. med. Wchnschr. 49: 1090, 1902.

There are four A-B-O blood groups, designated O, A, B, and AB, according to the International Classification. Their approximate percentages among representative American and European peoples are: O, 45 per cent; A, 42 per cent; B, 10 per cent; AB, 3 per cent.

There were two other classifications, Moss¹ and Jansky,² which are no longer used, but merely as a matter of record their equivalents according to the International Classification are given in Table 95.

The **International Nomenclature**, officially recognized by the Health Committee of the League of Nations, has been adopted. It is the same as the original classification of Landsteiner and von Dungern and Hirszfeld and is the nomenclature of choice; namely, O, A, B, and AB. To avoid confusion, it is urged that the group names of Moss and Jansky be eliminated from medical literature.

A further interesting communication upon blood groups was that by von Dungern and Hirszfeld,³ who discovered the existence of subdivisions in two of the four human blood groups.

It is interesting to note that the substances which characterize the four blood groups are present in practically every tissue of the body and have been found in soluble form in the serum, saliva, gastric juice, semen, urine, etc.

In addition to the foregoing facts regarding the primary four groups, Landsteiner and Levine⁴ noted that when certain immune sera from rabbits, previously injected with human blood, were absorbed with certain samples of human blood, they still contained agglutinins acting on the majority of bloods of all four groups, while other bloods were not agglutinated. Two of the factors demonstrable by these sera were designated **M** and **N**. They found that either the M or N agglutinogens or both were present in all human blood cells but no anti-M and anti-N agglutinins were found in the sera. These may be produced by injection of rabbits with the appropriate type of cells. Research since that time has shown that all human bloods may be divided into three types, M, N, and MN. The agglutinogens M and N are hereditary just as are the other blood groups originally described by Landsteiner. The **M** and **N** factors are of almost no importance with respect to blood transfusion work, for the reason that there are hardly ever any anti-M and anti-N agglutinins in normal human blood sera and M and N agglutinogens are apparently only feebly antigenic for human beings. They are important, however, in questions of determination of paternity, but are unreliable in the identification of blood stains. These facts are described on pages 1168 ff. and 1172 ff.

At What Age Do Agglutinogens and Agglutinins Appear in the Blood?—

Kemp⁵ showed that the isoagglutinin could first be demonstrated in the red blood cells of a fetus, 37 days old, and demonstrated that the sensitivity of the cells increases throughout antenatal and postnatal life up to the age of

¹Moss, W. L.: Bull. Johns Hopkins Hosp. 21: 63, 1910.

⁴Landsteiner and Levine: Proc. Soc. Exper. Biol. & Med. 24: 600, 941, 1927; J. Exper. Med. 47: 757, 1928.

⁵Acta pathol. et microbiol. scandinav. 7: 146, 1930.

20 years after which time it remains constant.¹ He also noted that the red blood cells of the newborn infant generally have only 20 per cent of the sensitivity to agglutination that adult blood cells have. Expressed in other terms, a serum with a titer of 500 against adult corpuscles would usually agglutinate the corpuscles of the newborn infant only up to a dilution of 1 to 100. Thompson and Kettel² determined the titer of the isoagglutinins in the sera of individuals of various ages. They found that isoagglutinins begin to appear in the latter half of antenatal life and rapidly increase in titer after birth up to the age of puberty. At this time, the titer gradually diminishes. It is generally considered that the average titer of the α (anti-A) isoagglutinin is higher than that of the β (anti-B) isoagglutinin. Wiener states that while isoagglutinogens are demonstrable at birth, only about half of all newborn infants have demonstrable isoagglutinins. Hirszfeld³ believes that any isoagglutinins at birth are derived from the mother by filtration through the placenta. Smith⁴ studied the isoagglutinin and isoagglutinin content of the blood of infants from day to day during the first few weeks of postnatal life and found that whatever isoagglutinins were present at birth diminished in titer or disappeared during the first ten days of life, after which time new isoagglutinins appeared.

Bornstein and Israel^{5, 8} made a study of agglutinogens in fetal erythrocytes, particularly the M and N agglutinogens. Moureau⁶ demonstrated the factors **M** and **N** in very young fetuses. Hyman⁷ found M and N demonstrable in three fetuses but failed to obtain either M or N in the fourth, 3 months old, whose cells exhibited the isoagglutinin B. She left the question open whether agglutinogens had disintegrated before expulsion of the fetus or whether they had not yet developed at that time.⁸ Bornstein and Israel's study comprised a larger series of fetuses to determine whether or not their agglutinogens are detectable with sera and testing fluids used in transfusion work and in legal tests. In addition, by including the Rh factor in the investigation, information can be obtained on the value of tests performed with fetal blood for investigations on isoimmunization as a cause of habitual abortion, according to Levine.⁹

Their series comprised nineteen premature fetuses, only those showing gross evidence of maceration being omitted. Blood was taken from the heart, suspended in physiologic saline solution, and examined the same day with the centrifuge method. In some cases examination of parents was possible. Various human A and B antisera and M and N testing fluids were used, which gave positive agglutinations with the corresponding cells in dilution of 1:8. For the Rh tests the test tubes were incubated for one hour at 37° C. before centrifugation.

⁹Levine, P., Burnham, L., Katzin, E. M., and Vogel, P.: *Am. J. Obst. & Gynec.* 42: 925, 1941.

The fetuses varied in length between 7 and 50 cm., the average being 28.6 cm. The distribution of agglutinogens was independent of the length of the fetuses and did not grossly deviate from the percentages in the population. No fetus without either M or N was encountered, and no combination parent M, fetus N, or vice versa occurred. The Rh factor was demonstrable in four out of five fetuses. This confirms the indirect evidence that the Rh factor is present early in fetal life as derived from Levine's work.

Table 93 gives the summary of their work :

TABLE 93.—BLOOD GROUPS AND BLOOD TYPES OF FETUSES AND PARENTS. PRESENCE OR ABSENCE OF RH FACTOR (TESTED IN NOS. 15-19 ONLY)

FETUS				
NO.	LENGTH	AGGLUTINOGENS	MOTHER	FATHER
1	21 cm.	O MN	O M	
2	7 cm.	O MN	B M	
3	13 cm.	A M	A M	
4	47 cm.	O MN		
5	23 cm.	A M		
6	13 cm.	O M	O MN	O MN
7	30 cm.	A MN	A MN	A MN
8	50 cm.	A M		
9	42 cm.	A N		
10	27 cm.	A MN		
11	19 cm.	O N		
12	26 cm.	B M		
13	30 cm.	A N		
14	33 cm.	B N	A MN	
15	41 cm.	AB M Rh+	A MN Rh+	
16	42 cm.	A M Rh+	O MN Rh+	
17	39 cm.	A MN Rh-	A MN Rh-	
18	17 cm.	O N Rh+	A N Rh+	
19	21 cm.	B MN Rh+	A MN Rh-	B N Rh+

This research demonstrated agglutination of A, B, M, N, and Rh in the heart's blood of nineteen fetuses. This seems to prove that agglutinogens are actually developed long before birth and in sufficient strength to make the examinations reliable enough for scientific purposes.

Composition of the A-B-O Blood Group System

Division of all bloods into four groups of the A-B-O system depends upon antibodies contained in the plasma and blood factors found in the cells. The substance in the cells is called *isoagglutinogen*, while the antibody in the plasma is called *isoagglutinin*. Now, at least 10 different blood group systems have been described; namely, the A-B-O, M-N-S-s, P, Rh-Hr, Lewis, Lutheran, Kell-Cellano, Duffy, Kidd, and U* blood group systems. For each system, one or more characteristics or factors have been identified.

The A-B-O group name is derived from the isoagglutinogen content of its cells. The isoagglutinins are designated as anti-A and anti-B, or by the Greek letters α and β , while the isoagglutinogens are designated by the Latin letters A and B. Isoagglutination, or the clumping of human blood cells by the action of an incompatible human serum, occurs when the specific isoagglutinin and isoagglutinogen are brought into contact with each other. Since anti-A is specific in its action on A isoagglutinogen, the sera of all bloods containing

*Wiener and Unger: J. A. M. A. 153: 1444, 1953.

anti-A will agglutinate the cells of all bloods containing the **A** factor. Similarly, the anti-B agglutinin of blood serum will agglutinate all blood cells containing the **B** factor. The names for most of the other systems were derived from the individuals in whom the antibody was first found.

There are two isoagglutinins, anti-A and anti-B, and two isoagglutinogens, A and B. Group O contains in its plasma both isoagglutinins anti-A and anti-B, while the red cells contain the isoagglutinogen O (or none). The group is identified by reason of the fact that its corpuscles are insensitive to the isoagglutinins, whereas its serum will agglutinate the red cells of all other groups. Group A contains in its plasma the isoagglutinin anti-B, while its erythrocytes contain the agglutinable substance A. Thus the plasma of group A will agglutinate cells of all groups containing the agglutinable substance B (groups B and AB), while its cells are agglutinated by all groups whose sera contain the anti-A isoagglutinin (groups O and B). Group B contains the isoagglutinin anti-A in its plasma, while the isoagglutinogen B is found in its cells. Thus the serum of group B will agglutinate all cells containing the A agglutinable factor (groups A and AB), while its cells will be agglutinated by all sera containing the anti-B isoagglutinin (groups O and A). Group AB contains no isoagglutinins in its serum, but its cells contain both the A and B isoagglutinogens. Its red cells are therefore agglutinated by sera of all other groups, while its serum has no action upon the red cells of any groups. These facts are seen in Table 94.

TABLE 94

In order to insure safe blood transfusions,* that is, in order to prevent what is known as incompatible reactions, certain preliminary examinations must be made of both the recipient's and the donor's blood. These are as follows: (1) Obtain the blood group of both the recipient and the donor by testing the cells against known sera anti-A (group B) and anti-B (group A), and

*Refer to page 1008.

check these results by testing each of the blood sera, previously inactivated, against known cells (A_1 and B); (2) obtain the subgroup if the recipient is group A or AB; (3) cross-match the recipient's serum with the donor's cells, and the recipient's cells with the donor's serum; (4) determine the Rh factor. Blood cells are grouped by testing the corpuscles with known anti-A and anti-B sera; sera are grouped by testing against known A_1 and B cells. The exact technic is given on pages 1003 ff.

Caution: A serologic test for syphilis should be performed on all prospective blood donors to exclude syphilis. It is well also to bear in mind the possibility of transmitting malaria in blood transfusion. It is recommended, therefore, that a thick drop and blood film examination should be made of all donors to detect malaria as well as any blood dyscrasia which would make the donor objectionable. It is well not to transfuse blood of an allergic individual.

Attention has been called by several writers to the effect of sulfanilamide on the cross-matching of blood. The author has several cases on record at the Christian Hospital of St. Louis of difficulty in cross-matching in patients undergoing sulfanilamide treatment which were not related to disease but were apparently due to some peculiarity of the blood brought about by this therapeutic agent in the blood stream.

One example of the effect of sulfanilamide on blood grouping occurred with a group B donor whose blood was of a very high anti-A titer. This donor was given sulfanilamide therapy following appendectomy, and for a period of three months following administration of the drug, his blood serum agglutinated not only A and AB blood cells, but also group B cells.

Summary of Facts on A-B-O Blood Grouping.—All agglutination reactions depend upon two factors, the substance causing the reaction, and the substances acted upon. Isoagglutination, or agglutination of human blood cells by incompatible human blood serum, is this type of reaction. The substance causing the reaction is called *isoagglutinin* and is present in the blood plasma or serum. The substance acted upon is called *isoagglutigen*, and is present in human blood cells. The isoagglutinins in the serum are designated as anti-A and anti-B. Blood serum may have both of the isoagglutinins, or either, or it may contain neither. The isoagglutinogens in the red blood cells are designated by the large Latin letters A and B. Cells may contain both A and B, or either A or B, or may lack both, in which case they are called O. ("O" is now considered a blood factor. Group O blood cells are now considered to possess a corresponding agglutigen O.) The reaction between isoagglutinins and isoagglutinogens, resulting in the clumping of the cells, is called *isoagglutination*. The anti-A agglutinin in the serum causes the agglutination of blood cells containing the A isoagglutigen, while the anti-B agglutinin in the serum causes the agglutination of blood cells containing the B isoagglutigen. If either the isoagglutinin or the isoagglutigen is lacking, there can be no reaction; hence, in a transfusion, it is necessary to inject into the blood stream of the recipient blood cells containing no isoagglutigen which might be acted upon by the isoagglutinin in the serum of the patient.

Blood Factor C of the A-B-O System*¹

It is necessary to understand the difference between an agglutinin and a blood factor. An **agglutinin** is a substance on the surface of the red cell. There are many agglutinins on the human red cell shared by all members of the species, and others which are type-specific, such as the A-B-O agglutinins, the M-N-S agglutinins, the Rh-Irr agglutinins, etc. Agglutinins are antigenic. Injection of human cells into a sensitive subject results in formation of antibodies which are capable of either clumping or lysing the red cells. An agglutinin can cause formation of and combine with more than one kind of antibody. The properties of agglutinins which enable them to combine specifically with their corresponding antibodies are known as "**blood factors.**"[†]

Every agglutinin has multiple blood factors which characterize it. For example, agglutinin M has multiple factors **M_i**, **M_{ii}**, **M_{iii}**, etc.

The agglutinin A has two principal blood factors, **A** and **C**, while agglutinin B has two main blood factors, **B** and **C**. Corresponding to the three blood factors **A**, **B**, and **C**, there are three naturally occurring isoagglutinins, anti-**A**, anti-**B**, and anti-**C**. Thus the composition of the four blood groups can be summarized as in Table 96.

TABLE 96.—COMPOSITION OF THE FOUR BLOOD GROUPS

BLOOD GROUPS	RED BLOOD CELLS		SERUM ISOANTIBODIES
	AGGLUTININOGENS	BLOOD FACTORS	
O	*	*	Anti- A , anti- B , anti- C
A	A	A and C	Anti- B
B	B	B and C	Anti- A
AB	A and B	A , B , and C	None

"O" is now considered a blood factor.

If group O serum is titrated for anti-A and anti-B, and then absorbed with cells of group A, there is usually appreciable reduction in the titer for B cells; absorption with cells of group B will usually reduce the titer for A cells. If, however, one pools anti-A and anti-B sera and then absorbs such pooled sera with A cells, the anti-B titer is not reduced, nor is the anti-A titer reduced if such sera are absorbed with B cells. Thus it seems reasonable that group O serum contains a third isoagglutinin, anti-**C**, specific for a blood factor **C** shared by agglutinins A and B.

It is relatively easy to prepare high-titered anti-A immune rabbit sera free of the **C** antibody, but anti-B immune sera are generally of considerably lower titer and contain a good deal of anti-**C**, which is difficult to remove by absorption. Thus, if antisera from immunized rabbits are used for blood grouping, many group A individuals will be incorrectly classified as group AB due to traces of anti-**C** agglutinins in the anti-B reagent, which will clump both A and B cells.

There is evidence of the existence of blood group C, with an incidence of 1 in 60,000 individuals. In a case cited by Wiener,² the red cells of the indi-

*Agglutinin O and factor O are omitted for the sake of simplicity.

†To avoid ambiguity, Wiener has proposed the use of bold-face type for symbols representing blood factors and their specific antibodies, regular type for agglutinins and phenotypes, and italics for the genes and genotypes.

¹After Wiener, A. S.: *Ann. Eugenics* 18: 1-8, 1953.

²*Ann. Eugenics* 18: 1-8, 1953.

vidual reacted as group O in tests carried out in the usual way with anti-A and anti-B grouping sera, while the serum agglutinated all cells of groups A and B, but not of group O. In addition, the cells are strongly agglutinated by *all* group O sera. Group O sera contain the isoagglutinin anti-C not present in sera of other blood groups, which seems to prove that his blood belonged to rare group C. The serum of this individual contained both anti-A and anti-B isoagglutinins.

Nonspecific Agglutination

False Negative Reactions.—If testing sera are of high titer, the reactions are so definite with the open slide method that it is practically impossible to mistake them. Using the protein media or whole blood technic, these might be reported negative if the specimen is not spread thin enough on the glass slide and if the drop of saline is not added at the end of the time limit for the reaction. When testing unknown sera against known cells, the antibody concentration is not controlled, and weak positive reactions might occur. The same is true in cross-matching, where the drops must be searched diligently for slight clumping. Likewise, antibody titer gradually decreases in ampuled sera, so that controls must always be made before using such testing sera.

Another source of error may be low sensitivity of agglutinogens, which is seen when testing blood of newborn infants or at times when using preserved blood suspensions. One of the most common errors is to mistake subgroup A₂B for blood group B, due to the weak reactivity of the A agglutino-gen in such blood. The use of high-titered anti-A sera will obviate such results.

Pseudoagglutination.—Pseudoagglutination is the false appearance of agglutination which is not true agglutination at all, but usually rouleaux formation of the red blood cells. It simulates true agglutination. It is produced by high concentration of serum and high temperatures. It occurs on the slide test because of the low dilution of the serum and because the large surface favors evaporation and concentration of the serum. Serum from patients with rapid sedimentation rates will produce rouleaux formation with any red blood cells, including their own.

One must be cautious in using gum acacia, gum tragacanth, and gelatin to avoid pseudoagglutination. Care must be exerted in reading reactions where trypsinated cells are used. A negative control prepared just like the test must always accompany such tests.

The difference between pseudoagglutination and true agglutination can be readily seen under a microscope. In rouleaux formation, the red blood cells are arranged in piles like coins. By adding a few drops of saline, rouleaux formation or pseudoagglutination will usually disappear, while true agglutination either is not affected by this procedure or at times is made even more apparent.

Bacteriogenic Agglutination, the Huebner-Thomsen or Panagglutination Phenomenon.—Bacteriogenic agglutination is a phenomenon unrelated to isoagglutination, and results from bacterial action. It does not occur when perfectly fresh blood and serum are used. It is seen in some samples of stored

blood where the cells are clumped by any normal human serum, including that of the individual from whom the blood was derived, and also by group AB serum.

Bacterial contamination also affects blood sera, which then cause agglutination of red cells of several groups as well as their own groups. It may be avoided by using only freshly drawn blood.

Autoagglutination.—Autoagglutination is a condition in which the serum agglutinates its own red blood cells, due to the presence of an absorbable agglutinin in the serum and a corresponding agglutinogen in the cells. Autoagglutinins act not only on the subject's own cells, but also on the cells of all other human beings, regardless of blood group, and are therefore panagglutinins. The reaction occurs usually in tests made at low temperature. It usually disappears upon warming and reappears upon chilling.

In certain pathologic conditions, the autoagglutination titer is considerably increased and the reaction may occur at room temperature. Such conditions are atypical pneumonia, paroxysmal hemoglobinuria, syphilitic or hypertrophic cirrhosis of the liver, hemolytic icterus, Raynaud's syndrome, trypanosomiasis of man and animals, severe anemias, and other conditions. These autoagglutinins at room temperature are a source of error in blood grouping, especially when the titer is high. In some cases it is impossible to perform a red blood count, as pointed out by Gradwohl in Hodgkin's disease and febrile tuberculosis.

It is suggested that whenever a patient's group is determined as AB, the serum be tested against A and B cells. This is a good practice for all blood groups, and is recommended in this chapter as a routine test.

The serum can be freed of the interfering autoagglutinins by separating it from the cells at 0° to 5° C., at which temperature the blood cells absorb the autoagglutinins. The cells should be washed with warm saline (37° C.) before cross-matching.

"Cold" Agglutination.—Cold agglutination is due to the taking up of adsorbable antibodies in the cooled state. Since cold agglutination occurs in human bloods exposed to temperatures from 0° to 15° C., and is prevented by higher temperatures, this factor must be borne in mind when conducting tests.

Secondary Coagulation Simulating Agglutination.—Tests made with unwashed cell suspensions often show secondary coagulation, or the presence of a clot. This does not occur with washed cell suspensions or when inactivated sera are used for the tests.

False Agglutination by Umbilical Cord Sera.—Wiener observed that some cord sera produced a phenomenon resembling true agglutination. While testing a series of cord sera with A and B blood cell suspensions by the open slide method, he found that when the slide was tilted back and forth the cells came together in clumps, but that these clumps broke up again if the slide was allowed to remain at rest. The process could be repeated indefinitely. It was demonstrated that Wharton's jelly from the umbilical cord was responsible for the phenomenon.

Isohemolysis

Certain unheated blood sera, when mixed with incompatible blood cells, will dissolve them instead of causing agglutination. This reaction occurs between sera of human blood and human blood cells and is not to be confused with hemolysis of certain blood cells by specific amboceptor sera. This reaction is due to isohemolysins normally present in the sera and not caused by any pathology in the individual. The isohemolysins correspond in specificity to the isoagglutinins normally found in human sera. Thus it is not unusual for serum of group O to hemolyze the blood cells of group A, or even B or AB. The sera of group AB individuals do not contain isohemolysins. Usually agglutination of the cells occurs first, followed by hemolysis. This is not necessarily true, for we have frequently observed the dissolving of erythrocytes without preliminary agglutination. In one instance, a group B serum caused hemolysis of both A_1 and A_2 cells without first agglutinating them when the serum was unheated. After inactivation, this same serum gave a titer of 1:80 against the A_1 cells, but required 10 minutes to agglutinate the A_2 cells.

Isohemolysis can be prevented by inactivating the serum at 56°C . for 30 minutes to destroy the natural complement. The blood drop in which isohemolysis occurs can be observed in the process of clearing even by macroscopic examination. The orange-colored suspension will be seen to clear and will take on a reddish cast. Observation under the microscope often will disclose some erythrocytes not yet hemolyzed.

Isohemolysis is important because it may mask isoagglutination, and if unnoticed may lead to incompatible blood transfusions. This would occur in cross-matching when blood from a different group is given to the recipient. It is overcome in the usual grouping test by inactivating A and B antisera.

TECHNIC OF BLOOD GROUPING¹

1. Reagents.—

(Method of Unger)

The following testing sera are needed for complete blood grouping tests for transfusions, including sensitivity testing for Rh-Hr antibodies, the A-B-O groups and M-N types, the antiglobulin (Coombs) test, and conglutination tests. All sera used for blood grouping work must meet the requirements for standards of potency (high titer) of the National Institutes of Health (NIH).¹

Anti-A serum	Anti-Rh ₀ conglutinating (slide) serum
Anti-B serum	Anti-Rh ₀ ' conglutinating (slide) serum
Absorbed B (anti-A ₁) serum	Anti-Rh ₀ '' conglutinating (slide) serum
Anti-M serum	Anti-hr' conglutinating (slide) serum
Anti-N serum	Anti-hr'' conglutinating (slide) serum
Coombs serum (antihuman globulin)	Anti-Rh ₀ saline agglutinating (tube) serum
30% bovine albumin (Armour)	Anti-rh' saline agglutinating (tube) serum

¹All blood testing sera, as well as whole blood and other fractions, are considered biologics under the Biologics Law. They must be licensed, prior to commercial distribution, by the National Institutes of Health, United States Public Health Service.

Witebsky group A
and group B
specific substance

Anti-rh'' saline agglutinating (tube) serum

Anti-hr' saline agglutinating (tube) serum*

Anti-hr'' saline agglutinating (tube) serum*

The following cell suspensions must be prepared daily.† They are usable for 24 hours. Prepare both saline-suspended untreated and trypsinated cells of the various blood groups:

Group O Rh₂Rh₀

Group O Rh₁Rh₁

Group O Rh₂rh

Group O rh'rh

Group O rh''rh

Group O rh

Group A₁ (rh)

Group B (rh)

Additional reagents needed are:

Trypsin, Difco 1:250

Physiologic (0.85%) saline

Phosphate buffer, pH 7.41, M₆15, Eimer and Amend

2. Equipment.—

The list of equipment used here was compiled from that used in Dr. Lester J. Unger's laboratory in New York City (New York University-Bellevue Medical Center, Blood Bank).

Microscope containing a scanning lens, 32 mm. 0.10 strain-free. If this is not available, simply remove the front lens attachment from the low-power objective of a microscope, and use the remaining lens system.

Electrically controlled water bath, which should be kept covered at all times.

An angle centrifuge. That made by Ivan Sorvall,‡ 27-tube head, with 18 holders in the outer circle and 9 on the inner, is excellent. The Phillips-Drucker (St. Louis, Mo.) centrifuge is also recommended (Fig. 231).

Racks for small tubes. We recommend those made by Standard Scientific Corporation, Catalog No. 95222, with 4 rows of 10 holes per row. The top and middle sections have $\frac{5}{8}$ inch holes, while the bottom of the rack has small ($\frac{5}{16}$ inch) holes.

Viewing box (Clay-Adams, etc.) (Fig. 232).

A Brewer automatic pipetting machine is excellent but not absolutely essential.

Ordinary glass slides, 3 in. by 1 in.

Glass slides 3 in. by 2 in.

10-cell Boerner slides, 57₈ by 180 mm.§

Clay-Adams 12-ring slides, containing baked-on red enamel rings.

Wooden applicators.

Droppers and rubber bulbs.

Capillary droppers.

Soda straws, to use in place of droppers (in addition to droppers listed above).

Gauze pads, 3 in. by 3 in., 12 ply.

Red wax pencil.

Blue wax pencil.

Cover glasses, $\frac{7}{8}$ in. square.

Tubes: 4 in. by $\frac{1}{2}$ in.

3 in. by $\frac{1}{2}$ in.

7.5 cm. by 8 mm.

B-D Vacutainer tubes for collecting specimens of blood.

*Not available (1955). Use Anti-hr'' slide serum.

†In a small laboratory, if all the cells are not available, use group O Rh₂, O rh, A₁, and B cells.

‡210 Fifth Ave., New York 10, N. Y.

§Made by Mercer Glass Works, Inc., New York.

Containers, about 250 c.c. capacity, of different shapes, for holding saline and waste saline during the blood grouping tests.

3. Special Anticoagulant Used for Blood Grouping.—

Ammonium oxalate.....	2 gm.
Potassium oxalate.....	3 gm.
Distilled water.....	100 c.c.

Put 0.2 c.c. in the *bottom* of each tube. Sterilize by dry heat.

Add 4.8 c.c. of venous blood and mix by inverting about 20 times to keep the blood from clotting. An excess of oxalate might cause false negative results in Rh testing.

Fig. 231.—The Comet centrifuge. (Courtesy Phillips-Drucker, St. Louis, Mo.)

Fig. 232.—Diamond viewing box. (Courtesy Clay-Adams Company, New York.)

4. Preparation of Plasma.—

Take blood as indicated in (3) above, using the special anticoagulant.

Shake to prevent clotting.

Centrifuge.

Remove enough plasma for cross-matching tests, sensitivity testing, and any other work required. Leave enough to resuspend the cells for the protein-media testing. See below. Exact method of removing plasma is given on page 1009, Fig. 237.

5. Preparation of 2 or 3% Cell Suspension in Physiologic Saline (Unknown Cells).—

Place about 1 c.c. of saline in a Kahn tube (3 in. by $\frac{1}{2}$ in.).

Dip a straw into the cells left over from step 4, and add to the saline, mixing in and out of the straw until a 2 or 3% suspension is obtained. This is judged by the color (tomato juice).

If clotted blood has been submitted, loosen the clot with a wooden applicator, centrifuge, remove the serum, use some of the cells shaken from the clot to make the saline suspension. Wash once in saline and resuspend to a 2% concentration with saline.

6. Preparation of Control Cell Suspensions.—**(a) Untreated Saline-Suspended:**

Prepare cell suspensions as outlined in (5) above.

Centrifuge to pack cells.

Remove supernatant saline.

Shake tube to loosen cells.

Add saline to a 2 or 3% suspension (color of tomato juice). This is referred to as washing once with saline.

(b) Trypsinated Saline-Suspended:

Trypsin must be prepared daily. Use Difco trypsin, 1:250.

Use the Eimer and Amend (or other brand) phosphate buffer solution pH 7.41, M/15.

Put a small amount of trypsin (about one-quarter inch in a Wassermann tube) into a small tube, 5 by ½ inch.

Add enough phosphate buffer to make a supersaturated solution.

Centrifuge. Remove the supernatant fluid and place it in another tube.

Wash a saline suspension of desired cells 4 times in saline.

Pack after the last washing by centrifuging and removing the supernatant fluid.

To 9 drops of packed washed cells

add 1 drop of freshly prepared trypsin.

Shake and place in a water bath at 37° C. for 1 hour, shaking every 15 minutes while in the water bath.

Wash once with saline. (Add saline, centrifuge, remove supernatant trypsin, add saline, shake.)

Resuspend to 5% concentration in saline.

If kept refrigerated, trypsinated-saline suspended cells can be kept for 1 or 2 days. If some hemolysis occurs, wash once with saline and resuspend cells in fresh saline.

(c) Cells Suspended in Own Plasma (Unger).—

Add cells from the whole blood to some of the plasma removed from the whole blood, until a 2 to 5% suspension has been reached.

For routine work, group A₁, group B, group O Rh_zRh₀* cells are used; for titrations, group O Rh₁Rh₁, group O Rh₂rh, group O rh'rh, group O rh''rh, group O rh.

7. Preparation of Protein Media Cells Suspended in Their Own Plasma (C₅₀), 50% Suspension.—These will be referred to as "Whole Blood."

After centrifuging whole oxalated blood, remove part of the plasma until there are equal parts of plasma and cells.

Shake to resuspend the cells.

Whole blood is used for slide Rh testing, both with unknown and control blood, and for testing for A-B-O factors by the rapid slide method.

8. Using Droppers to Maintain a Standard Drop.—

In order to maintain standard drops throughout a test, and also to save time and equipment, the following method, as suggested by Unger, can be used.

Have three containers, approximately 250 c.c. capacity, each of a different shape so as not to confuse them. One is for saline for use in the test, one is for rinsing saline, and one is for discarded saline, cells, and plasma.

(a) Discharge material left in the dropper into the waste container, wiping off the outside of the dropper with a gauze pad.

(b) With the bulb still squeezed, pick up a dropperful of rinsing saline and discharge it into the waste container, and continue squeezing the bulb.

(c) Wipe off outside of dropper, and, still squeezing the dropper, pick up another dropperful of rinsing saline, discharge it into the waste container, and continue 5 or 6 times. Be sure to wipe off the outside of the dropper.

*Agglutinated by all 5 antisera: Anti-rh', Anti-rh'', Anti-Rh₀, Anti-hr', and Anti-hr''.

(d) With the bulb still squeezed so as not to admit anything from the dropper into the clean saline, pick up a dropperful of saline from the saline for use, and use what is needed, discharging the excess into the waste container. Always hold the dropper at the same angle when measuring drops for a test. Do not admit bubbles from a dropper, for this would be less than a full drop.

If handling serum or plasma by this method, discharge excess remaining serum or plasma from the dropper into the waste container and not back into the original specimen.

9. Preparation of Slides for Blood Grouping, Rh Testing, and Cross-Matching.—

Wax ring slides may be used (see below) for testing saline-suspended cells by the open slide method.

When using whole blood (protein media), prepare slides by drawing a large oval $1\frac{1}{2}$ in. by $\frac{3}{4}$ in. with a red wax pencil.

10. Preparation of Saline.—See page 2033.

CAUTION: When the sera are not in use, they must be kept refrigerated. Always protect the testing sera against bacterial contamination.

All work should be read by at least two technicians, without access to the records of each other. If there is any discrepancy in the results, the tests should be made again.

The cell suspensions used for the day's work should be prepared fresh each day at the same time, preferably by the same technician.

Preparation of Wax Rings

The use of paraffin ring slides has been alluded to. These are prepared in the same manner as for use in the Kline test. Prepare the slides by cleaning well to render them fat-free and make rings of wax with the usual contrivance furnished by the manufacturer, using melted paraffin to make the double circles of wax on the slide. The capacity of each one is about 0.05 c.c., so that in making the grouping test, small drops of serum and cell suspensions

Fig. 233.—Ten-welled slide for blood grouping. (Courtesy Arthur H. Thomas Co., Philadelphia.)

should be used. Serum and cell suspensions are mixed by rotating the slide on its flat surface or tilting it back and forth 4 to 10 minutes, after which the reactions are read with the naked eye and with the microscope. By using a tray which can hold three of the paraffin ring slides, as many as 36 tests can be performed at one time.

An improvement over the wax rings on glass slides is that entailing the use of the Boerner micro test slides (Fig. 234). These test slides are 88 mm. long, 58 mm. wide, and 2 mm. thick, with rounded corners and twelve mold-pressed, raised rings, 15 mm. top diameter, in three rows of four each, numbered consecutively from 1 to 12. The bottoms of the cells are flat and slightly rounded at the periphery, which construction prevents capillary flow around the outer edge of the bottom and insures thorough shaking of the drop. It also permits rapid macroscopic and microscopic examination. While they were designed

for use in the Boerner-Jones-Lukens microflocculation test, they are very satisfactory for blood grouping procedures. A case of wood, with hinged lid, may be purchased from Arthur H. Thomas Company to house the slides, keeping them clean and preventing breakage, scratching, etc., when not in use. (See Fig. 235.) A more recently designed slide is seen in Fig. 233.

Fig. 234.

Fig. 235.

Fig. 234.—Boerner micro test slide. (Courtesy Arthur H. Thomas Company, Philadelphia.)

Fig. 235.—Case for holding Boerner micro test slides. (Courtesy Arthur H. Thomas Company, Philadelphia.)

Fig. 236.—Boerner electric rotating apparatus. (Courtesy Arthur H. Thomas Company, Philadelphia.)

Blood grouping tests are facilitated by using the Boerner electric rotating apparatus. (See Fig. 236.) This gives perfect shaking of blood grouping slides and has an automatic cut-off timing device, with speed control rheostat and motor with worm reduction gear and driving mechanism which rotates the platform in a horizontal plane so that it circles an area $\frac{3}{4}$ inch diameter to simulate hand rotation.

Outline of Blood Grouping Tests Made Routinely on Patient and Donor

(For other tests, refer to pages 1060 ff.)

1. Test for A-B factors on the patient's cells (and even if blood bank blood is available, on the donor's cells), using a 2 or 3 per cent suspension of cells in saline against known anti-**A** and anti-**B** sera.

2. At the same time, run controls on the antisera, using known group A₁ and group B, preferably type rh, cell suspensions in saline. The anti-A serum must agglutinate A cells but not B, and the anti-B serum must agglutinate B cells but not A.

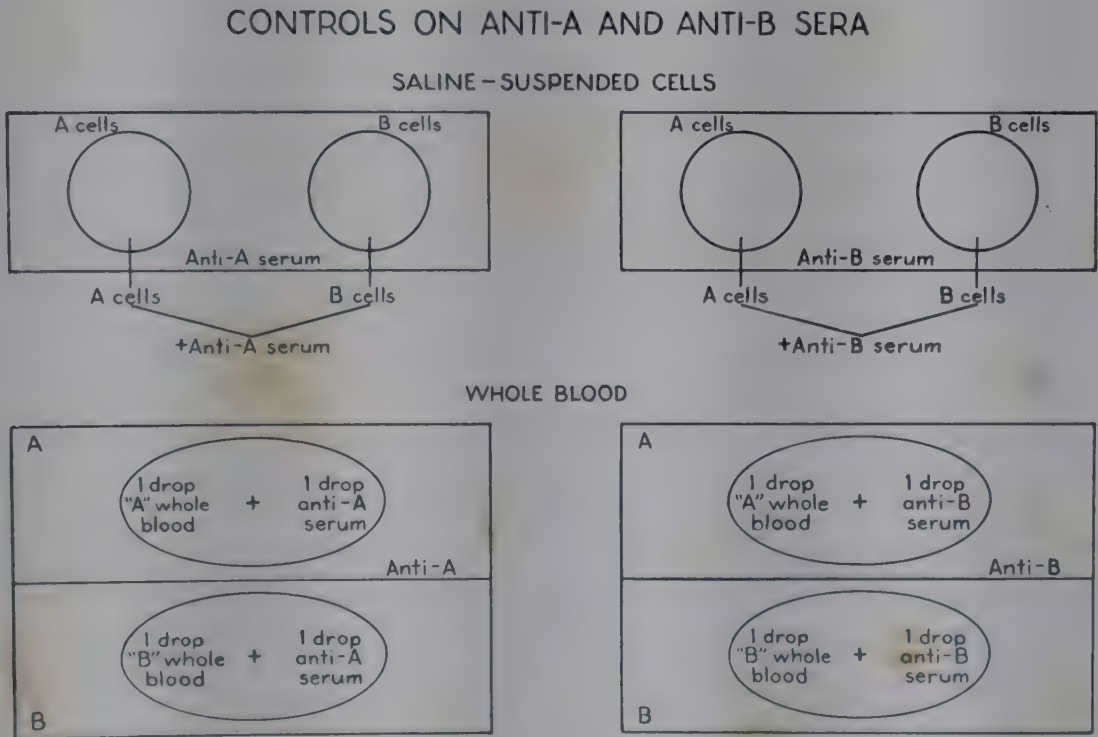

Fig. 237. (After Unger.)

3. Test the plasma (serum) of the patient (and the donor even if blood bank blood is available) against known group A₁ and group B cells suspended in saline. If isohemolysis occurs, inactivate the serum (plasma) and re-test.

4. Test the whole blood of the patient (and donor even if blood bank blood is available) against anti-A and anti-B sera, using the open slide method.
5. If the results in 1, 3, and 4 differ, repeat the tests; an error has been made.
6. Subgroup all A's and AB's by testing the cells against absorbed anti-A serum. This is not essential for ordinary blood transfusion work.
7. Test the patient's whole blood for the **Rh₀** factor by the slide agglutination test, using anti-**Rh₀** conglutinating (slide) serum. If the result is negative, consider the patient *Rh-negative*, and use only *Rh-negative* donor blood, even though the patient's blood might contain the **rh'** and **rh''** factors. Proceed to step 9 whenever possible.
8. Test the donor's whole blood against anti-**Rh₀**, anti-**Rh'**, and anti-**Rh''** conglutinating (slide) sera. If the blood is positive by any of these three, DO NOT GIVE IT TO AN Rh-NEGATIVE PATIENT. If using blood bank blood where all the tests are run, it is usually possible to obtain a type rh (triple Rh-negative) donor.
9. If the patient is Rh-negative by the slide test, perform an Rh tube test, using the washed cells, 2 or 3 per cent suspension in saline, against known anti-Rh saline-agglutinating (tube) sera. Test for **Rh₀**, **rh'**, **rh''**, and the **Rh₀** variant (**Rh₀**). If all are negative, the patient is type rh (triple Rh-negative), and thus **hr'** and **hr''** positive.
10. Cross-match (a) the donor's cells against the patient's serum (plasma)
(b) the patient's cells against the donor's serum (plasma)
using the cells suspended in saline, incubating in a water bath, reading macroscopically and microscopically. If the results of this test are negative, make an antiglobulin test on the cell sediment. See 12 below. If the results are positive, reject the donor.
11. Make an open slide protein media (conglutination) cross-matching test, using (a) donor's whole blood against patient's serum (plasma) and (b) patient's whole blood against the donor's serum (plasma).
12. At the same time as the cross-matching tests are run (10, above), make an Rh-sensitivity test, using the patient's serum (plasma) against group O Rh_zRh₀ cells (cells which are agglutinable by anti-**Rh₀**, anti-**rh'**, anti-**rh''**, anti-**hr'**, and anti-**hr''** sera):
 - (a) untreated and suspended in saline
 - (b) trypsinated and suspended in saline
 - (c) 2 or 3 per cent suspension in their own plasma.
13. It is well to make sensitivity tests of the donor's serum or plasma.
14. If any of the cross-matching tests are positive, reject the donor.
15. If the donor's plasma shows sensitivity to the Rh-Hr factors, reject the donor.
16. In all cases of pregnancy, make a sensitivity test on the mother's blood, and if positive, titrate for antibody concentration. Repeat the titration throughout the pregnancy as requested by the physician in charge of the case. (See page 1073.)
17. In unexplained erythroblastosis fetalis, test mother's serum for antibodies other than the Rh-Hr antibodies, and in the presence of an A-B-O incompatibility, titrate the A and B antibodies.

CONTROLS ON Rh ANTISERA

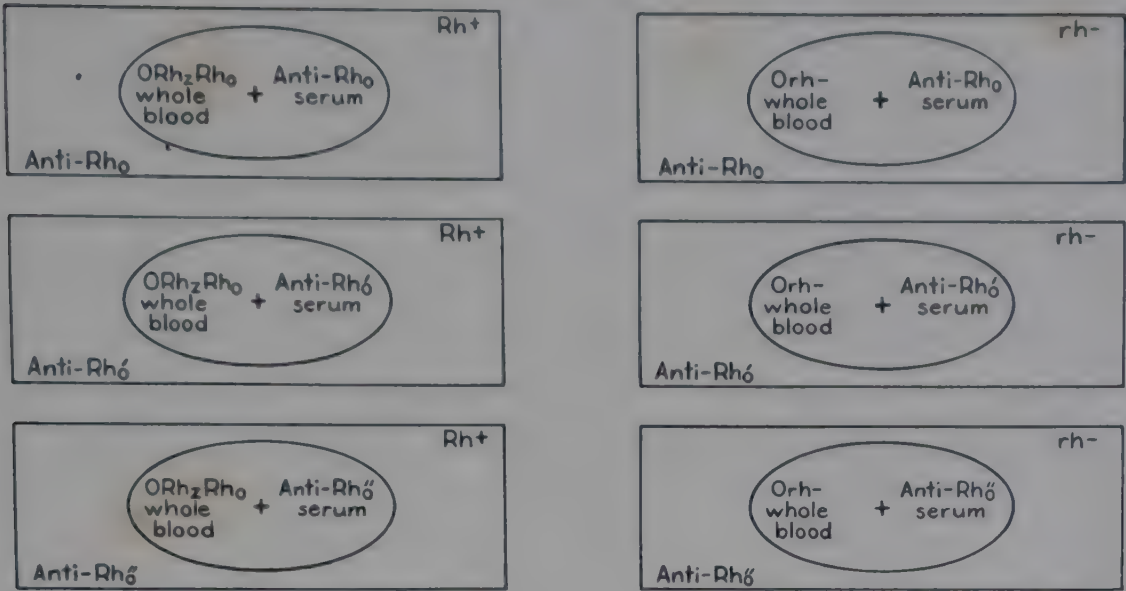

Fig. 239.

TESTS ON PATIENT AND DONOR

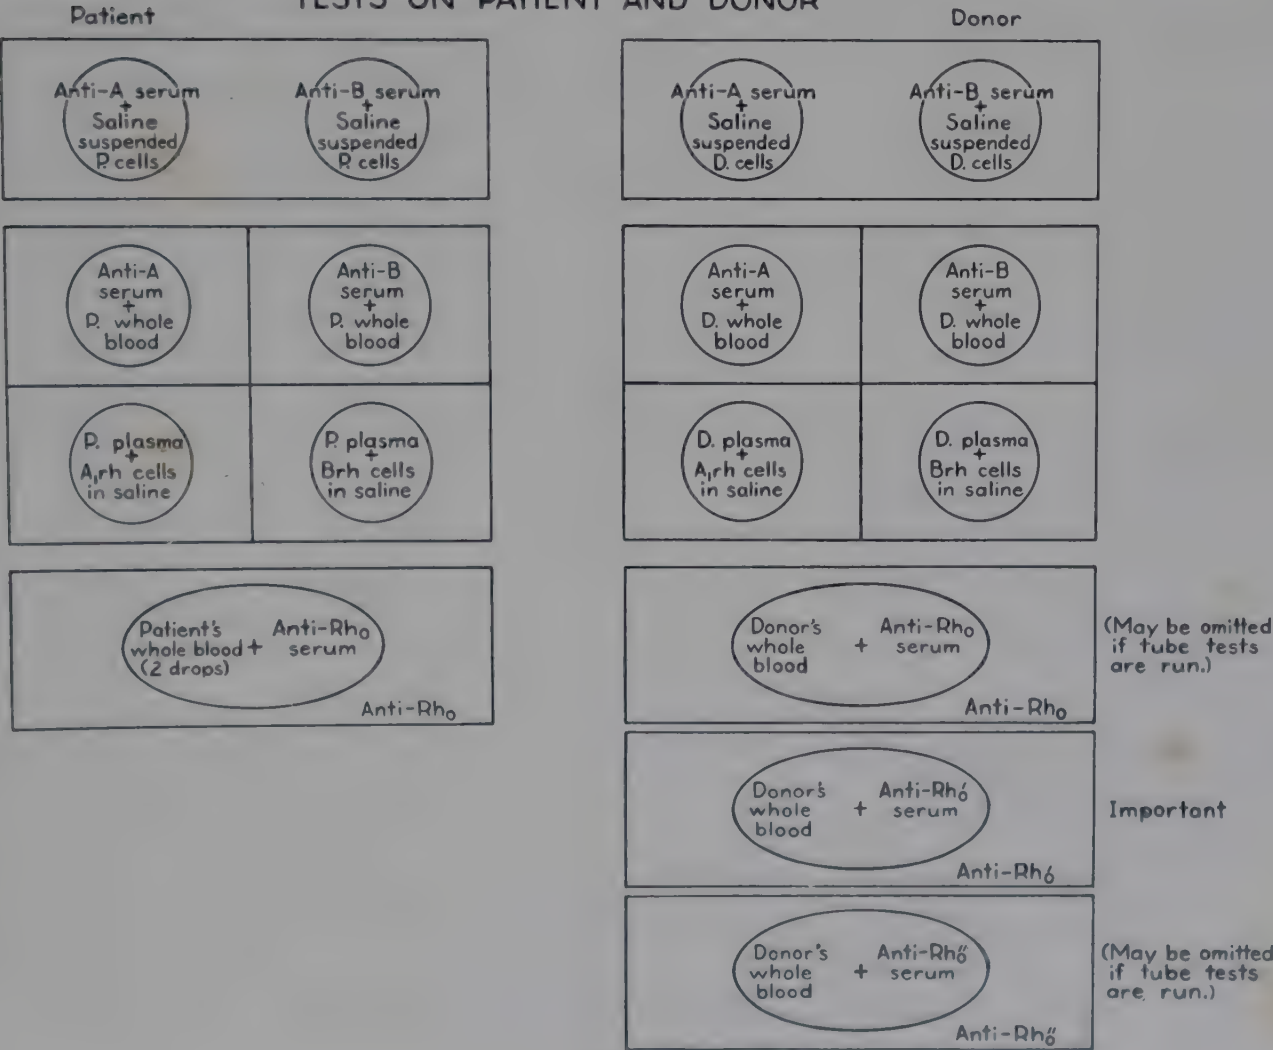

Fig. 240.

(I) Testing Unknown Cells to Determine Blood Group

(A) Using Saline-Suspended Cells.—

Controls

Have on hand glass slides containing two wax rings. (See Fig. 238.)

Label the left side “A” cells and the right side “B” cells.

Label the first slide “anti-A” serum and the second slide “anti-B” serum.

Place 1 drop of group A₁ cell suspension in the left-hand ring of each slide, and 1 drop of group B cell suspension in the right-hand ring of each side. (See page 1005 for preparation of cell suspensions.)

Add 1 drop of anti-A serum to each ring of the first slide, and 1 drop of anti-B serum to each ring of the second slide. Take care that the tips of the droppers do not touch the cells.

Mix and rotate, examining macroscopically and microscopically, under the low power without the Abbé condenser, at the end of five minutes, and again after eight minutes. Add a drop of saline to each ring before taking the final readings. Results expected are seen in Table 97.

TABLE 97

	“A” CELL SUSPENSION	“B” CELL SUSPENSION
Anti-A serum	+ (Agglutination within 45 sec. to 3 min.)*	- (No agglutination)
Anti-B serum	- (No agglutination)	+ (Agglutination within 45 sec. to 3 min.)*

*Good sera usually cause clumping within 10 seconds.

Agglutination must be + + +, and lack of agglutination must **not** be doubtful (see description below and page 1016). Anti-A serum must agglutinate the A cells but not the B, while the anti-B serum must agglutinate the B cells but not the A.

If the proper results are obtained, grouping of the cells of the donor and the recipient may be undertaken, using these anti-A and anti-B sera. If agglutination does not take place properly, or if the results are not correct in any way, discard the sera and obtain fresh reagents.

The Actual Test

Using a slide with two wax rings, label the left side “anti-A” and the right side “anti-B.” Place the individual’s name or laboratory number in the center of the slide for identification. (See Fig. 240.)

Place a drop of the unknown cells in each ring.

Add 1 drop of anti-A serum to the left side and 1 drop of anti-B serum to the right side. Take care that the tips of the droppers do not come into contact with the cell suspensions.

Mix and rotate, examining macroscopically and microscopically (under low power without the condenser). Record a positive reaction whenever it occurs, but wait eight minutes before recording a negative. At the end of the eight minutes, add a drop of saline to each ring, rotate thoroughly to mix, and read again. Record agglutination as a positive reaction and lack of agglutination as a negative reaction. If there is any doubt about the reaction, repeat the test.

Agglutination occurs as brick red clumping of the cells, the clumps being completely separate from each other. Lack of agglutination is simply the homogeneous suspension of the cells as they appear when suspended in saline. Do not confuse settling of the cells and rouleaux formation of the reds with true agglutination.

True agglutination is not affected by the addition of saline, while rouleaux are broken up with the addition of saline. See pages 1001 ff. for a discussion of false reactions. Avoid working in drafts or where cold air currents can blow over the open slides.

Determine the blood group by consulting Table 98.

TABLE 98. IDENTIFICATION OF BLOOD GROUPS, USING UNKNOWN CELLS

UNKNOWN CELLS PLUS ANTI- A SERUM	UNKNOWN CELLS PLUS ANTI- B SERUM	GROUP
-	-	O
+	-	A
-	+	B
+	+	AB

- = no agglutination; + = agglutination.

(B) Using Cells Suspended 50 Per Cent in Their Own Plasma (Whole Blood).—

Controls

Prepare slides as described under the actual test. (See Fig. 238.)

Label the slides A cells + anti-A, B cells + anti-A, A cells + anti-B, and B cells + anti-B.

Place about $\frac{1}{2}$ drop of known A whole blood in the slides labeled "A cells," and the same quantity of B whole blood in the slides labeled "B cells."

Add 2 drops of anti-A serum to each slide labeled "anti-A," and 2 drops of anti-B serum to each slide labeled "anti-B."

Mix and spread each with a separate wooden applicator.

Place on a lighted viewing box and handle as for the actual test (below).

The reactions should be the same as those in Table 97; a positive reaction should occur within 1 minute. Take the final reading in 5 minutes, after adding a drop of saline on each slide. Do *not* read microscopically.

The Actual Test

Prepare slides, 3 in. by 2 in., by making red wax oval rings $1\frac{1}{2}$ by $\frac{3}{4}$ in., two such rings on each slide.

Label one ring "anti-A" and the other "anti-B."

Label with the name or laboratory number of the individual being tested.

Place the whole blood to be tested in each ring by just touching the slide with the wet straw so that only a fraction of a drop is placed on the slide.

Add 2 drops of anti-A serum (of very high titer) to its proper ring, and 2 drops of high titer anti-B serum to its proper ring.

Mix each ring thoroughly and spread with a different wooden applicator.

Place on a lighted viewing box, and tip downward. Allow to remain on the box for 5 minutes, rocking back and forth occasionally. At the end of 5 minutes, read for clumping or lack of clumping.

With the box tipped downward, add a drop of saline to the top of each ring, and let it run down into the test. If rouleaux are present, the saline will break them up, but true agglutination will remain.

Determine the blood group, after waiting another 3 minutes, rocking the box back and forth, by consulting Table 98.

If the results using the whole blood and the cell suspensions are the same, proceed with the test, using the plasma or serum as the unknown; if they are different, an error has been made, and the tests must be repeated.

(II) Testing Unknown Serum or Plasma to Determine Blood Groups

In order to determine the blood group using serum or plasma as the unknown, it is necessary to have at hand cell suspensions of known group A₁ and B bloods, preferably rh, washed once and resuspended to 2 or 3 per cent concentration in saline. See page 1006.

If time permits, inactivate the serum at 56° C. for 30 minutes to destroy complement, and prevent subsequent hemolysis if the serum contains an iso-hemolysin. If an isohemolysin is present in a serum along with the corresponding isoagglutinin, the opposing cells begin to clump, then dissolve, and the reaction is very difficult or impossible to read. Isohemolysins will not act except in the presence of complement, which is destroyed at 56° C. When the complement is destroyed, the isoagglutinin acts in the usual manner, being thermostable, and the usual agglutination reaction takes place.

Use a slide with two wax rings. Label the slide with the name or laboratory number of the unknown. Label "A cells" at the left side of the slide and "B cells" at the right side.

Place 1 drop of known A₁ cells in the ring labeled "A cells" and 1 drop of known B cells in the ring labeled "B cells." (Fig. 240.)

Add a drop of the unknown serum or plasma to be tested to each ring.

Mix and rotate in the usual manner. Read a positive reaction as soon as it occurs, but do not take a final reading on a negative reaction until 8 minutes have passed. Read all reactions both macroscopically and microscopically. Agglutination may be strong or weak, depending upon the concentration of antibodies in the unknown serum.

Do not wait too long before reading, or surface drying takes place and pseudoagglutination may occur.

Add a drop of saline to each ring, mix again, and take a final reading under the microscope.

Determine the blood group of the unknown by consulting Table 99.

TABLE 99

A ₁ CELLS PLUS UNKNOWN SERUM	B CELLS PLUS UNKNOWN SERUM	GROUP
+	+	O
-	+	A
+	-	B
-	-	AB

Explanation: This is a test to determine anti-**A** and anti-**B** agglutinins in the unknown serum. Group O serum contains both anti-**A**, which agglutinates A cells, and anti-**B**, which agglutinates B cells. Group A serum contains anti-**B**, which agglutinates B cells but not A. Group B serum contains anti-**A**, which agglutinates A cells but not B. Group AB serum does not contain either anti-**A** or anti-**B** agglutinins, and therefore cannot agglutinate either A or B cells.

If the result in this test differs from the result obtained when testing the unknown cells against anti-**A** and anti-**B** sera, that is, if a different blood group is obtained, repeat both tests, but using different antisera and cell suspensions.

Preparation of Anti-A and Anti-B Testing Sera

Preparation of the Sera.—The testing sera must be of a high degree of potency (titer). It is a mistake to use testing sera that do not meet the standards of the N.I.H. It is a mistake to pool different lots of anti-**A** and anti-**B** sera and use them for testing purposes unless each of the pooled sera is of high titer. No anti-**A** serum should be used for testing purposes unless it will agglutinate A₁ cells at a 1:256 dilution, A₂ cells at a 1:128 dilution, A₁B cells at a 1:128 dilution, and A₂B cells at a 1:64 dilution. No anti-**B** serum should be used to test unknown bloods unless it will agglutinate B cells at a 1:256 dilution. These are the requirements of the National Institutes of Health. Unless one uses great quan-

tities of the testing sera, it is much better to purchase them already prepared and standardized. Be sure to examine for the expiration date, and use only those manufactured under special license, in order to avoid grave errors in blood grouping tests.

Select a group A_1 individual with a high titer serum, and without Rh antibodies. Use sterile precautions throughout the procedure of obtaining and preparing the serum. Remove the blood by venous puncture, either with a sterile 20 c.c. syringe or, if blood is desired in larger quantities, use the commercially available vacuum bottles without anticoagulant. If using the smaller quantity, eject the contents of the syringe, under sterile precautions, into a clean, dry, sterile 50 c.c. Rockefeller tube, and immediately cork. Label with the name of the person from whom derived, the group letter, and the titer. Allow the blood to clot with the tube in a slanting position. Loosen the clot by striking the tube against the palm of the hand, and centrifuge at high speed for 30 minutes.

Observing all sterile precautions, carefully remove the supernatant serum by means of a sterile dropper, placing it in a clean, dry, sterile tube labeled with the name of the person from whom derived, the group letter, and the titer. Immediately cork. Inactivate at 56° C. for 30 minutes to destroy the natural complement to prevent subsequent hemolysis, and to kill any contaminating bacteria.

Transfer this with sterile precautions to sterile ampules and hermetically seal. Label with the name of the donor, the group letter, the titer, and the date. Store in a refrigerator.

Save enough of the serum to re-test before using. Test against A_1 , A_2 , and B cells, suspended in saline, and also use the whole blood. The anti-**A** serum must agglutinate the A_1 and A_2 cells but not the B, while the anti-**B** serum must agglutinate the B cells, but not the A_1 or A_2 . If any other results are obtained, or if the reactions are not strong, or require too long a time to take place, do not use the serum.

Titration of the Sera.—It is necessary to titrate anti-**A** serum against A_1 , A_2 , A_1B , and A_2B cells, and anti-**B** serum against B cells, so that one does not use sera which are too weak to detect properly the blood groups of unknown blood. Weakly reacting sera will give false negative results in the grouping tests, which may lead to serious transfusion reactions. Three examples of each group of cells should be used.

In all titrations, serial dilutions of each serum are made, and each dilution tested against the opposing cells. The highest dilution of the serum which causes agglutination of its specific cells is called the titer. Many different methods of titrating sera have been proposed, but we prefer the method of Unger which follows.

Making the Dilutions for Titrations.—The sera should be inactivated at 56° C. for 30 minutes and allowed to cool to room temperature before dilution. Prepare serial dilutions of sera of 1:1 (undiluted), 1:2, 1:4, 1:8, 1:16, 1:32, 1:64, 1:128, 1:256, 1:512, and any other dilution desired or needed.

Use racks which hold 10 tubes per row. Rack up tubes 7.5 cm. by 8 mm., 10 per row, one row for each type of cells used. If titrating anti-**A** serum, four rows will be needed. If titrating anti-**B** serum, only one row will be needed.* These are the titration tubes. Refer to Fig. 254 for set-up for titrations.

At the same time, rack up two rows of Kahn tubes, 10 per row. These are the dilution tubes.

Use serum, not plasma, for titrations.

Place the serum in the first tube of the front row of Kahn tubes. Be sure that all tubes are properly labeled.

In all the back rows of dilution rack, add saline to fill the tubes. This will be used to rinse the dropper. There are now two rows of dilution tubes, the first row empty except for the first tube which contains serum, and a back row of 10 tubes filled with saline.

Put a drop of undiluted serum to be tested into the first tube of each row of the titration tubes.

Carry 10 drops from the first tube of serum to the second tube in the front row of dilution tubes.

Rinse the dropper with all the saline in tube 1 of the back row of dilution tubes, and remove the discarded saline tube from the rack. Wipe off the excess saline with a gauze pad.

*If anti-**B** is titrated against A_1B and A_2B , three rows will be needed.

Put 10 drops of clean saline, using the same dropper at the same angle, into each tube of the front row of dilution tubes, beginning with tube 2.

Use the same dropper throughout the procedure and hold it at the same angle.

Mix the contents of tube 2 thoroughly in and out of the dropper, taking care to avoid bubbles.

Put a drop of this 1:2 dilution of serum into the second tube of the titration racks, and carry 10 drops to tube 3 of the dilution tubes.

Rinse the dropper with all the saline behind tube 2, and wipe off the excess with a gauze pad.

Mix the contents of tube 3 (1:4 dilution) of the dilution tubes thoroughly, carry a drop to tube 3 of each titration row, and 10 drops to tube 4 of the Kahn tubes for dilutions.

Again rinse the dropper, using the saline in the tube behind tube 3, and continue the dilutions and disposal of drops as before, until all the dilutions have been made and the titration racks contain 1 drop of the respective dilution per tube: 1:1 in the first tube, 1:2 in the second, 1:4 in the third, 1:8 in the fourth, 1:16 in the fifth, etc. See Fig. 254.

Add 1 drop of the opposing cells* suspended in saline to each tube, using the same dropper after rinsing thoroughly with saline as directed above. This insures the same size drop for both serum and cells.

Leave for 2 hours at room temperature. Tip the rack so that the bottoms of the tubes are visible and take bottom readings. Negative reactions run down in a pear-shaped formation. Agglutination reactions usually remain round.

Flick the tubes and gently spread the contents over the tube, and read under a scanning lens of a microscope. Or remove a small amount of sediment from each tube and examine under a microscope.

Reading Results.—It will be noted that the clumps of blood cells gradually become smaller as the serum becomes weaker. With some sera, one dilution of serum may show strong agglutinating powers, while the next dilution shows a clear negative reaction. Report as *three plus strong* (+++s) any complete agglutination; that is, there are large brick-red clumps clearly visible to the naked eye, with no unagglutinated cells present. A *three plus weak* (+++w) reaction would be complete agglutination, but with smaller clumps. A negative (-) reaction is absence of any signs of agglutination microscopically or macroscopically. Record reactions as +++s, +++w, ++s, ++w, +s, +w, ±, and -. The last dilution in which there is definite agglutination is considered the titer.

Examples of Titrations

1:1	1:2	1:4	1:8	1:16	1:32	1:64	1:128	1:256	1:512	TITER (UNITS)*
++w	-	-	-	-	-	-	-	-	-	1½
+++s	+++s	++w	+s	+w	-	-	-	-	-	16
+++s	+++s	+++s	+++s	+++s	+++w	+++w	++s	+w	±	256
+++s	+++w	+++w	++s	+	+w	-	-	-	-	32

*The titer (in units) is the reciprocal of the highest dilution of serum giving a one-plus reaction.

Obviously, the first serum would be of no value for laboratory testing purposes. This blood would, however, yield ideal plasma, because of the low isoagglutinin content.

Subgroups and Groups A and AB

Von Dungern and Hirszfeld¹ first called attention to the fact that when a group B serum was absorbed with certain group A bloods until it lost the power of agglutinating the absorbing blood, the serum still agglutinated most other bloods of group A and group AB. They suggested a subdivision of groups A and AB. In 1923 this was further emphasized by Coca and Klein.²

*See page 1015.

¹Zeitschr. f. Immunitäts. 8: 526, 1911.

²J. Immunol. 8: 477, 1923.

This resulted in the recognition of the fact that there are subgroups of A and AB; namely, A_1 and A_2 , and A_1B and A_2B . In other words, in the sera of group B and group O individuals, there are isoagglutinins acting on the isoagglutino-gen A. According to the common concept this isoagglutinin is a single entity designated as anti-A. The so-called α or anti-A isoagglutinin is composed of a number of qualitatively different fractions, of which there are two main varieties; (1) anti-A isoagglutinin proper, reacting with both isoagglutinogens A_1 and A_2 with approximately equal intensity, and (2) isoagglutinin anti- A_1 , which reacts with isoagglutino-gen A_1 but practically not at all with isoagglutino-gen A_2 . Different B and O sera contain these two isoagglutinin fractions in varying quantities and proportions.* Two different B sera which react with A_1 cells at approximately the same titer may have different titers when tested against A_2 cells. If, for instance, such sera contain very much anti- A_1 , and very little of the common anti-A isoagglutinin, there might be a titer of 40 for A_1 cells and a titer of only 5 for A_2 cells. On the other hand, another serum which contains a large proportion of common anti-A isoagglutinin might have a titer of 20 to 40 for A_2 cells even though the titer for A_1 cells is no greater than that of the first serum. In some cases B serum may react distinctly on A_1 and practically not at all on A_2 cells. In the case of AB blood, the danger of using such sera for testing purposes is great, since the sensitivity of A_2 isoagglutino-gen in this group is greatly diminished and such blood is readily mistaken for group B. It is for this reason that every group B serum used for grouping purposes should be titrated against A_2 as well as A_1 cells. Since A_2 makes up approximately one-fourth to one-fifth of all group A individuals, it is manifestly clear that with weak anti-A testing sera 20 to 25 per cent of group A individuals may be erroneously diagnosed as group O.

It is, therefore, important that in all grouping tests one must subgroup all A's to determine whether they belong to A_1 or A_2 classification. After the regular grouping tests have been done, take out all the A's and determine which are A_1 's and which are A_2 's. This is carried out with what is known as absorbed B (anti- A_1) serum.

Preparation of Absorbed B (Anti- A_1) Serum.—Observe all sterile precautions throughout the entire process. If the serum is contaminated, it will lose its agglutinating powers and will give false results. Place a few c.c. of sterile 3.8% sodium citrate in a sterile 50 c.c. Rockefeller tube and replace the cork immediately. Withdraw blood with a syringe from the vein of an individual of subgroup A_2 and place with sterile precautions in the sodium citrate solution. Cork and mix well to prevent coagulation. Wash three times with sterile 0.85% saline (see page 2043 for the washing of blood cells), and pack by centrifuging. Discard the supernatant fluid after the last washing. These cells are the packed, washed A_2 cells. When possible absorb with pooled A_2 cells derived from a number of individuals.

Place group B (anti-A) serum, obtained under sterile precautions, in a 50 c.c. sterile Rockefeller tube, and inactivate at 56° C. for 30 minutes. Add one-third to one-fourth as much of the packed, washed, pooled A_2 cells. Cork and mix back and forth. Allow the mixture to stand for one-half hour at room temperature, inverting occasionally, and centrifuge to separate the serum. Remove and keep the supernatant fluid, which is absorbed B (anti- A_1) serum. It will usually be found that the serum recovered no longer reacts with A_2 cells, but still agglutinates A_1 cells distinctly.

*Wiener, A. S.: *Am. J. Clin. Path.* 9: 145, 1939.

To Test Absorbed B (Anti-A₁) Serum.—Have on hand three known A₁ and three known A₂ cell suspensions. These are prepared in the usual manner (see page 1005).

Place a drop of each cell suspension in a wax ring on a slide properly labeled and add a drop of absorbed B (anti-A₁) serum to each one.

Rotate and observe every 30 seconds under the low-power objective of the microscope until 5 minutes have elapsed. A₁ cells should be agglutinated within 1 or 2 minutes, while the A₂ cells should not be agglutinated at the end of the 5- to 10-minute period. If neither A₁ nor A₂ cells have been agglutinated, discard the serum. If the A₂ cells agglutinate in less than 5 minutes, repeat the absorption, using less A₂ cells than during the preceding absorption period, and reducing the time of absorption to guard against over-absorption. Test the serum again against known A₁ and A₂ cells.

Technic of Subgrouping A and AB Blood Cells (Using Absorbed B [Anti-A₁] Serum)

(1) **Controls.**—The reagent used for subgrouping groups A and AB cells is absorbed B (anti-A₁) serum. When using an absorbed serum it is necessary to limit the time between making the test and reading the reaction, since many absorbed sera are slightly underabsorbed and may give false reactions after a prolonged time period. In order to determine the *time element* in reading subgrouping tests, it is well to make controls on the serum just before using, testing it against known A₁ and A₂ cell suspensions. Prepare suspensions of known A₁ and known A₂ cells. Place a drop of known A₁ cells in a wax ring on a slide properly labeled, and a drop of known A₂ cells in another ring also properly labeled. Add to each drop one drop of absorbed B (anti-A₁) serum. Rotate and observe under the low power of the microscope until agglutination takes place, recording the time required to agglutinate A₁ cells. A₂ cells should remain unagglutinated for at least 8 minutes, but if the serum is not completely absorbed, they may eventually be agglutinated by the serum. Record the time the first small clumps appear in the A₂ cell suspension ring. The test on the unknown cells must be read within this time limit. For example, A₁ cells were agglutinated in 1½ minutes, but A₂ cells did not begin to agglutinate before 10 minutes. Read the test on unknown A or AB blood cells at the end of 6 or 7 minutes.

(2) **The Actual Test.**—On a glass slide containing one wax ring, labeled with the name of the unknown and the group letter (either A or AB), place one drop of the unknown cell suspension. Add 1 drop of absorbed anti-A serum and rotate. Read microscopically under the low power without the Abbé condenser. Read periodically but record the reaction at the end of the time limit determined in the controls. Report agglutination as positive and lack of agglutination as negative. A positive reaction means that the subgroup is A₁ or A₁B as the case may be. A negative reaction means that the subgroup is A₂ or A₂B. Tables 100 and 101 give these results in chart form:

TABLE 100		TABLE 101	
A CELLS PLUS AB-SORBED ANTI-A SERUM	SUBGROUP	AB CELLS PLUS AB-SORBED ANTI-A SERUM	SUBGROUP
+	A ₁	+	A ₁ B
-	A ₂	-	A ₂ B

Agglutinogens A₃ and A₄.—In 1935 Fischer and Hahn¹ reported the occurrence of individuals of group A whose blood gave only feeble reactions even with the most potent anti-A sera. Friedenreich, reporting on the same phenomenon, conceded that the weak reactivity of such bloods was due to a third sort of A isoagglutinogen; namely, A₃. This isoagglutinogen A₃ gives rise to two additional subgroups in group A and AB; namely, subgroups A₃ and A₃B, respectively. These subgroups can be detected without any special method by their weak reactions with anti-A sera. A₃ blood, like A₂ blood, is agglutinated by sera containing anti-A₂ isoagglutinin. A₃ sera contain anti-B

¹Ztschr. f. Immunitäts. 84: 177, 1935.

isoagglutinins just like ordinary group A sera, but, as in A_2 sera, anti- A_1 cold isoagglutinins may be present in these and in A_3B sera. The existence of the A_3 receptor may account for certain errors in blood grouping.*

Wiener and Silverman report an interesting case belonging to group A_3 . This individual belonged to group A but showed weak agglutination reactions with anti-A sera, both those obtained from group B human beings and those prepared by immunizing rabbits with human A blood. Blood of this case gave a very weak agglutination with anti-A sera while the A_2 cells as well as the A_1 cells gave prompt and marked agglutination.

Microscopically, this patient's blood showed many free cells. With weak anti-A sera, these writers stated that the patient's blood might fail to react. That she belonged to group A was further established by testing her serum against standard O, A_1 , A_2 , and B cells. With the B blood, prompt agglutination was obtained, demonstrating the presence of the anti-B isoagglutinin. No reaction occurred with O or A_2 bloods, but a weak reaction occurred with the test with A_1 cells. Therefore, this patient's serum contained, in addition to the anti-B isoagglutinin, an irregular isoagglutinin anti- A_1 . These observers felt justified in placing this blood in the subgroup A_3 .

An A_4 blood group has been described by Gammelgaard and Marcussen.¹ There is a weak reaction of the A_4 with B sera. A further serologic characteristic is a reaction with certain O sera and immune sera of rabbits, which is stronger than in B sera. An irregular agglutinin for A blood corpuscles was proved in the sera of 13 out of 15 cases. A_4 was found only once in routine examination of 60,000 blood samples. The presence of A_4 was proved in 24 persons of a family of 64 members. The importance of the A_4 group lies in a possible mistaken identification by reason of the very weak reaction, which is further lowered in combination with agglutigen B. The A_4 group will rarely be revealed in routine serologic examinations of sera; therefore, in transfusions it may easily happen that blood of the A_4 group instead of O group is used. The A_4 group is comparable in its importance in legal medicine to that of the A_3 group, provided the hereditary process is clarified.

Cross-Matching

After the blood group and Rh type of the patient have been established, and a donor of the same blood group and Rh type has been tentatively selected, cross-matching tests must be made. That is to say, one must match the donor's cells with the patient's serum and the patient's cells with the donor's serum, and there must be no signs of agglutination of the red cells. It is well to make sensitivity tests for Rh-Hr antibodies at the same time as the cross-matching tests are run. See page 1062 for the method.

Caution must be exercised in accepting blood grouping designations by other laboratories. Remember that the person making the transfusion is responsible for whatever accident may happen; therefore, all donors and recipients must be re-grouped or re-typed when they appear for examination or transfusion. This is in no way intended to criticize the work of other laboratories, but is simply a measure of precaution which each one must follow.

*Also see Wiener, A. S., and Silverman, L. J.: *Am. J. Clin. Path.* **11**: 45, 1941.

¹Gammelgaard, A., and Marcussen, P. V.: *Ztschr. f. Immunitäts.* **98**: 411, 1940.

Another procedure, which is mentioned only to be condemned, is to do cross-matching *alone*, omitting blood grouping.

Correct cross-matching results can be obtained only on bloods of the same group or subgroup. That is to say, one may match the cells of the so-called "universal donor," group O, with the serum of almost every other individual, but the reverse gives incompatible results. Since cross-matching does not usually detect Rh incompatibilities, it is necessary to make Rh tests on both patient and prospective donors and to carry out the conglutinin method.

From time to time it was claimed by some that cross-matching tests preliminary to transfusions were superfluous. It was erroneously believed that if the A-B-O blood grouping tests were properly carried out on the blood of the patient and donor, and if the results showed them of the same blood group, there would be no danger of a transfusion reaction. Unger found this to be incorrect.¹ Unger was the first to report that occasionally serum of a patient would clump cells of a donor even though they both belonged to the same A-B-O blood group, and that transfusion of such blood was followed by chills and fever which he attributed to the observed incompatibility. He called the antibodies responsible for the intragroup incompatibility "minor" agglutinins to distinguish them from the anti-A and anti-B agglutinins. He used a 2 per cent suspension of the cells in the individual's own plasma to carry out these cross-matching tests, although at that time it was customary to use saline-suspended cells. He had unwittingly carried out the "conglutination" test and detected the univalent antibodies (blocking antibodies) although he did not identify them. Most likely some of these may have been Rh antibodies.

With the development of blood banks, there has been a great increase in the number of patients transfused and the number of transfusions given to the same patient. These repeated administrations of blood expose patients to a great variety of antigens, and they may become sensitized, since it is practically impossible to transfuse a patient with blood that is identical with his own with respect to all blood factors. There are now known to exist more than 50,000 varieties of blood. Perhaps some day a complete blood grouping may become as distinctive as a thumb print, as predicted by Karl Landsteiner.

The following specimens are needed for proper cross-matching tests: 2 or 3% suspension of patient's cells in saline, 50% suspension of patient's cells in its own plasma (whole blood), and patient's serum or plasma. The same specimens are needed from each prospective donor.

(A) Tube Method of Cross-Matching (Fig. 241).—

Saline Agglutination Test.—

Use tubes 4 in. by $\frac{1}{2}$ in. for cross-matching.

Place in a rack, in two rows. Two tubes are required for cross-matching one donor's blood with one recipient's blood. If more than one donor is available, run two tubes for each donor.

Label the back tubes "DS," for donor's serum, and the front tubes "PS" for patient's serum. Identify each tube with the correct name or laboratory number.

Place 2 drops of the donor's serum in the back tube.

Place 2 drops of the patient's serum in the front tube.

Add 2 drops of patient's cells, suspended in saline, to the back tube.

Add 2 drops of the donor's cells, suspended in saline, to the front tube.

¹Unger, L. J.: J.A.M.A. 76: 9, 1921.

Mix and incubate in a water bath at 37° C. for ½ hour.

Centrifuge at 500 r.p.m. for 2 minutes.

Pick up a small amount of the sediment from each tube, with a straw or a dropper, and place on a properly labeled slide. Put a cover glass over each drop.

Examine under the low power of a microscope, looking for clumping or lack of clumping. If clumping of the cells has occurred, reject the donor. Examine the slides very carefully.

CROSS MATCHING AND Rh-Hr SENSITIVITY TESTING FOR ANTIBODIES IN SERUM

Fig. 241. (Unger.)

If the results are negative, examine the contents of the tubes under a scanning lens of a microscope, by spreading the sediment the length of the tube, with gentle rocking of the tube. If clumping appears, reject the donor.

This is a control over the slide reading.

If the results are all negative, proceed with a Coombs test.

Coombs Test (Antiglobulin Test).—

Coombs tests are made when the results in the cross-matching test are *negative*.

Shake the tubes, add saline to the capacity of the tubes, centrifuge, and remove the supernatant saline. This is the first washing.

Shake the tubes, again add saline, and recentrifuge. Remove the supernatant saline and discard. This is the second washing.

Repeat for a third washing.

Remove the saline, turn the tubes upside down, and pat against a gauze pad to remove all traces of the saline from even the lip of the test tube.

Gently shake the tubes to loosen the cells.

Add 1 drop of antihuman globulin or Coombs serum to each tube.

Mix. Incubate in a water bath at 37° C. for 5 minutes.

Centrifuge at low speed, 500 to 1,000 r.p.m., for 2 minutes.

Gently dislodge the sediment and read over a lighted viewing box and under a scanning lens of a microscope.

If any signs of clumping occur, reject the donor.

When A-B-O compatibility has been proved, this test detects isosensitization of the serum to one or more factors of the blood it agglutinates.

(B) Slide Method, Using Whole Blood (Protein Media, Unger) (Fig. 241).—

Prepare a slide 3 in. by 2 in., by drawing two large oval rings the length of the slide and half the width.

Label the upper ring "PS" and the lower ring "DS" (patient's serum; donor's serum). Identify with the name or laboratory number.

Place 1 drop of patient's serum and 1 drop of donor's whole blood in the upper ring.

Place 1 drop of the donor's serum and 1 drop of the patient's whole blood in the lower ring.

Mix each with a different wooden applicator, spreading over the entire area of the ring.

Place over a lighted viewing box and tilt back and forth for 5 minutes, observing for clumping. *Do not read microscopically.*

At the end of 5 minutes, tilt the box, add a drop of saline to the top of each drop, and let it run down the drop. This is to break up rouleaux which might have formed.

If there are any signs of clumping, reject the donor. If there is no clumping, the cross-matching tests are compatible.

Some laboratories prefer the conglutinin method of cross-matching to the Coombs test. However, this is not good practice because the conglutination method cannot detect anti-*Duffy*. This can be detected only by the anti-globulin method.

(C) Conglutinin Method of Cross-Matching, Wiener.*—

Carry out the test in 2 small Kahn tubes.

Place two drops of recipient's serum in a tube marked "RS."

Place two drops of donor's serum in a tube marked "DS."

Add two drops of 30% bovine albumin to each tube.

Add *one* drop of 2% suspension of donor cells in saline to the tube marked "RS."

Add *one* drop of 2% suspension of recipient cells in saline to the tube marked "DS."

Do not add more than one drop of cell suspension to either tube.

Incubate for 3 to 5 minutes at 37° C.

Centrifuge for 2 minutes at 1,000 r.p.m.

Dislodge the cell sediment very gently. Excessive shaking may break up agglutination. Observe for agglutination or lack of agglutination.

When A-B-O group compatibility is proved, agglutination in the tube marked "RS" indicates that the recipient is immunized against a blood factor of the donor cells. Further cross-matching with other donor bloods must be carried out until blood is found which will not be agglutinated by the recipient's serum. Before testing with other donor bloods, the Rh type of the recipient must be carefully determined.

When Rh-positive recipients are immunized to Rh-positive blood belonging to a different Rh type, and when Rh-negative recipients are erroneously designated Rh-positive and isoimmunized, incompatibility with the donor blood may be detected by this method.

*Wiener, A. S. *Am. J. Clin. Path.* 12: 302, 1942.

Simple Blood Matching

Blood matching is not recommended since it assumes that the donor belongs to a group different from that of the recipient. According to older ideas, group O was a universal donor and could be used to give blood to all four groups, while AB was the universal recipient and could receive blood in a transfusion from all other groups. It was considered safe for all groups to give blood to their own groups and to group AB, and for all groups to receive blood from their own groups and from group O. In the light of later investigations, this arrangement has been shown to be dangerous.

Simple blood matching is still used in some laboratories, but it is not recommended. This test is made by mixing recipient's blood serum with the donor's cells, and observing for signs of agglutination. If any clumps of blood cells are seen, no matter how small the clumps, the donor is rejected.

The P Factor

Landsteiner and Levine,* in 1928, described an agglutinin P in human blood, more frequently found in Negroes than in whites. They demonstrated this factor with immune rabbit serum. Occasionally a natural irregular anti-P agglutinin is found in human serum, which acts on the P agglutinin in human cells. The reaction is extremely weak but may sometimes be demonstrated if the test is made in small tubes and not centrifuged, but kept in a water bath at 20° C., shaken occasionally, then examined under the microscope.

Anti-P agglutinins have been found in the sera of certain animals, such as, rabbits, hogs, cats, and cattle.

Landsteiner and Levine concluded that the property P is not a single, well-defined entity, but a group of related agglutinogens.

Occasionally anti-P agglutinins are found in normal human sera and are of sufficiently high titer to be usable as diagnostic reagents. Anti-P sera have been prepared from selected sera from P-negative professional donors containing an exceptionally high titer of natural P agglutinins.

Tests for P agglutinin are at times helpful in special problems of incompatibility in blood transfusions. The tests have also been used in anthropologic investigations, and in serologic studies on individual differences in human blood.

The P agglutinin is inherited as a simple Mendelian dominant by a pair of allelic genes designated *P* and *p*, respectively. The tests can therefore be used in medicolegal cases of disputed parentage, though this is not recommended.

The names "type P" and "type pp" are used instead of terms P positive and P negative. There are also bloods containing a variant of the P agglutinin.

Genotypes of P are *PP* and *Pp*; of pp are *pp*. Approximately 75 per cent of Caucasoids and 98 per cent of Negroids have been found to belong to type P, while 25 per cent of Caucasoids and only 2 per cent of Negroids have been found to belong to type pp. The percentage of type P among Mexican Indians has been found to be 78.9.

AGGLUTINOGEN Rh IN HUMAN BLOOD

Rh-Hr Nomenclature*

Two principal methods of designation of the Rh-Hr types are currently in use, the original Rh-Hr nomenclature and the C-D-E symbols. Significantly, the nomenclatures interpret the same set of observations differently, and so both cannot be correct. The Committee on Medicolegal Problems* has analyzed the available information in order to resolve this problem. Their conclusion is that the C-D-E notations "make no allowance for the difference between a blood factor and an agglutinin, and make the tacit incorrect assumption that every agglutinin has but a single corresponding antibody. . . . The Committee therefore recommends that the C-D-E notations for the Rh-Hr types be discarded, and that the original Rh-Hr nomenclature be retained as the sole nomenclature for this blood group system."

Reports of post-transfusion reactions when bloods of homologous groups have been transfused, where preliminary tests have been made by experienced observers using reliable and potent sera, indicate that these reactions represent intragroup incompatibilities. Cases of this type have been observed with unusual frequency following primary transfusions given to pregnant or postpartum women. It is believed that these represent an example of isoimmunization.

Isoimmunization

Isoimmunization was first noted by Ehrlich and Morgenroth¹ in 1900. *Heteroimmunization* means immunization of a member of one species by a member of another species. *Isoimmunization* means immunization of a member of a species by another member of the same species. Isohemolysins were produced in the goat by injecting erythrocytes of other goats. In the Ehrlich and Morgenroth goat blood injections, the immune, not normal, isoantibodies hemolyzed the cells from the goats that furnished the original inocula and also the cells of some, but not all, other goats. The serum did not contain an autolysin; that is, it did not affect or combine with the cells of the animal in which the antibody was formed. Their observations showed the possibility that a considerable number of different antigens might exist in similar cells of different individuals in a single species and also showed that an animal will not ordinarily produce antibodies to antigens that are present in his own blood. An animal can form antibodies against some of his own proteins or other components of his tissues, for example, the substance of the crystalline lens, casein,² and an alcohol extract of brain,³ but these materials are blood-foreign and thus satisfy one of the primary prerequisites for antigenicity. Immune isoantibodies have been produced in other animals and fowls (Wiener⁴).

It is difficult to perform isoimmunization experimentally in man. Thomsen⁵ attempted to immunize men by intramuscular injections of incompatible blood, but no significant rise in isoagglutinative titer was observed. This apparent evidence against the isoantigenicity of the A and B group-substances is, how-

*From Medicolegal Applications of Blood Grouping Tests, Supplementary Report; A Report of the Committee on Medicolegal Problems, American Medical Association, prepared by A. S. Wiener, R. D. Owen, C. Stormont, and I. B. Wexler. In press, 1956.

ever, outweighed by the positive evidences which will be presented in reference to the Rh factor. Thomsen's negative result is probably attributable to the relatively small quantity of blood injected, or, possibly, the route of injection was influential in his negative results. Thalhimer⁶ reported a case which is an example of the isoantigenicity of group-substance B. Here, a boy received 300 c.c. of his father's blood; cross-matching showed no incompatibility but no tests were made to determine the two blood groups. Only a mild febrile reaction ensued. Eighteen days later, without further tests, the father again served as donor; an alarming reaction stopped the transfusion after 150 c.c. of blood had been introduced. Subsequently, the bloods were grouped; the son was found to be group O and the father group B. Although no agglutinative titers were determined, it is probable that the anti-B normally present in group O plasma (with anti-A) was too weak to be detected by the ordinary test, and that the primary transfusion of group B blood served as an immunizing stimulus leading probably to a marked rise in the titer of anti-B, which thus intensified the incompatibility. There is further evidence that A and B are isoantigenic in Jonsson's⁷ finding that the maternal isohemagglutinins anti-A and anti-B are of higher titer when the corresponding antigen, A or B (not present in the mother's blood), is present in the blood of the fetus than when it is absent (transplacental isoimmunization).

Wiener⁸ recorded two cases which illustrate isoimmunization of A₂ individuals to A₁ blood. In one, the antigenic stimulus was provided by transfusion of A₁ blood; in the other, the source of the antigen was a fetus in utero. Because of the presence of immune anti-A₁ isoagglutinins in these patients' sera, only A₂ donors were used in subsequent transfusions, with satisfactory results. These workers presented evidence which indicated that had A₁ donors been used, hemolytic reactions most likely would have resulted. However, the absence of reports in recent literature indicates that subgroups A₁ and A₂ are not as important in transfusion as formerly believed.

Further, Wiener and associates state that in selecting donors for subgroups of A and AB, it is probably safe to disregard the subgroups except in the rare cases where the patient's serum contains an irregular isoagglutinin anti-A₁ or anti-A₂. Where the irregular isoagglutinin is present, only donors of the homologous group should be used. In this connection, the author cites a case* of a recipient of the A₂B class who had a severe reaction following donation of A₁B blood. Later, transfusion with A₂B blood resulted in no reaction. This probably corresponds with the irregular isoagglutination mentioned by Wiener.

Davidsohn⁹ maintained that the subgroups A₁, A₂, A₁B, and A₂B are significant in causing some post-transfusion reactions, but direct support of this possible mechanism was lacking until Wiener's¹⁰ report was published. Wiener analyzed a case of isoimmunization of an A₂ recipient by transfusion of A₁ blood. The anti-A₁ behaved like a "cold" agglutinin. In another case, anti-A₁

antibody was considered to have developed in an A_2 woman as a result of isoimmunization by an A_1 fetus in utero. The general explanation was first presented by Levine and Stetson¹¹ as the mechanism of reactions following primary intragroup transfusions given intrapartum or postpartum.

The formation of anti-O isoagglutinin in low titer has been observed in a group A_1B patient.¹² This suggests that the production of immune anti-O isoantibodies may possibly be a factor to be considered in repeated transfusions of blood from universal donors.

Isosensitization may result not only from repeated blood transfusions but also from intramuscular injections of blood or repeated pregnancies or a combination of these, and such isosensitization may in turn be responsible for post-transfusion hemolytic reactions. The development of isoantibodies requires at least two exposures to the antigen, with an interval of several months between each exposure. The first exposure primes the individual, and subsequent exposures stimulate the production of antibodies. In some cases, a long interval is not always necessary, isosensitization resulting from continuous stimulation over a short period of time, with huge quantities of the antigen being given. Unger¹³ cites the case of an Rh-negative male patient who received 5,500 c.c. of Rh-negative blood, and then, because the patient was moribund and no more Rh-negative blood was available, he was given 54,500 c.c. of Rh-positive blood within a period of 7 days. Rh sensitization tests were negative until the one hundred eighth pint of blood was to have been administered, when it was found that the patient had developed univalent Rh_0 antibodies.

The Rh Factor

It was formerly believed that dangerous transfusion reactions could not occur if both donor and recipient belonged to the same Landsteiner blood group. Between 1921 and 1939, with the increasing use of blood transfusion, authenticated reports of hemolytic reactions began to appear in the literature. These hemolytic reactions occurred in spite of the fact that all blood grouping tests, including the cross-matching test, showed donor and recipient of the same group and apparently compatible. Apparently Unger¹⁴ reported the first case of intragroup incompatibility. Although both patient and donor belonged to group O, on cross-matching he observed some clumping of the cells. When much blood was transfused, the patient developed chills and fever. Unger believed this reaction was hemolytic in nature. He postulated the existence of two different antibodies, the anti-A anti-B, which he called the "major" agglutinins, and another antibody which he called the "minor" agglutinin. His technic for cross-matching suspended the cells in serum rather than in saline; he therefore inadvertently, even at that early date, was carrying out the conglutination test. Possibly he was detecting the Rh_0 univalent antibody, although he did not identify it.

In most of the subsequently reported cases, no explanation of reactions could be found. In a few instances, the patient's blood serum was found to

contain *irregular isoagglutinins* and *isohemolysins*. The irregular isoantibodies acted on the blood of the donor used in the transfusion, as well as on certain other human bloods, independently of the blood groups. Among the most carefully studied instances of this sort were those reported by Unger,¹ Zacho,² Culbertson and Ratcliffe,³ Neter,⁴ and Levine and Stetson.⁵ No attempt, however, was made to correlate these cases and the subject remained in this stage until Landsteiner and Wiener reported their discovery of the Rh factor and explained its role in the reactions in retransfusions.

Landsteiner and Wiener in 1937 detected the presence of M-like agglutinogens in the blood of rhesus monkeys and they found that the injection of the blood of rhesus monkeys into rabbits stimulated the production of anti-M agglutinins. Previously, Schiff found that the injection of sheep blood into rabbits caused the formation of anti-A agglutinins and hemolysins. Landsteiner and Wiener continued their research in the hope that by the use of animal blood instead of human blood for preparing antisera they might discover new factors in human blood. They did find that some of their antisera for rhesus monkey blood contained an agglutinin reacting with the blood cells of 85 per cent of the Caucasoid population, quite independently of the blood groups or M, N, and P factors. They designated this factor *Rh* to indicate the manner in which it was first discovered,⁶ using the first two letters of the word rhesus. They did not immediately report their findings because they wished to do further work on their antisera. In 1939 Wiener and Peters found three cases of hemolysis following transfusions of blood of the homologous groups, which were proved to be due to isoimmunization to the rhesus factor. Thus, this new blood factor became clinically very important,⁷ and the cases were reported. Wiener stated in his Alvarenga Prize Lecture⁸ that this was the reason why the Rh factor, found by Landsteiner and Wiener in 1937, was first announced in January, 1940.

Briefly, the blood cells of 85 per cent of all Caucasoid individuals are agglutinated by anti-rhesus (anti-Rh₀) sera. These cells contain the Rh agglutinin identified by the factor designated as **Rh₀**. These individuals were called Rh positive, while the remaining 15 per cent were called Rh negative. These Rh-negative blood cells do not possess the **Rh₀** factor and therefore are not agglutinated by anti-**Rh₀** sera. Since 1940, other Rh factors have been found, **rh'**, **rh''**, **rh^w**, and the variant **Rh₀**, along with other factors. See discussion on pages 1034 ff.

The Rh Factor in Retransfusions

In connection with blood transfusion, Wiener demonstrated that the Rh agglutinin is antigenic to man. Thus, Rh-negative individuals may become sensitized to the **Rh₀** factor as a result of the transfusion of Rh-positive blood, and then cannot again safely receive Rh-positive blood. Rh-negative indi-

viduals, except in dire emergencies, should be transfused only with Rh-negative blood, and then only if no Rh antibodies are present in the donor's serum. The rules for the Rh factor as applied to the operation of a blood bank are described by Unger.⁹

It is much safer to transfuse all Rh-negative individuals with group O Rh-negative blood only, or with Rh-negative blood compatible with their own blood groups. In respect to the transfusing of females from birth to the climacteric, if they are Rh negative and are transfused with Rh-positive blood, they may develop Rh antibodies. These qualities may persist for life, so that if another transfusion is required and Rh-positive blood is used, severe transfusion reactions may occur. Particularly the fact must be borne in mind that these Rh-negative females, who have been transfused at some time in their early life with Rh-positive blood, are isoimmunized to the Rh factor; so that when undertaking marriage and upon becoming pregnant, if the fetus is Rh positive they will most certainly have severe intragroup transfusion reactions if transfused with Rh-positive blood. If the fetus is Rh positive their chances of bearing normal infants are endangered.

The Rh Factor in Primary Transfusions of Pregnant Women

The Rh types of blood are hereditarily determined,¹⁰ the **Rh**₀ factor being transmitted as a single Mendelian dominant by a pair of allelic genes, *R* and *r* (*R* determines Rh-positive; *r* determines Rh-negative). Since every individual possesses a pair of genes from every series of allelic genes, one being derived from the mother, and the other from the father, there are three genotypes possible. Rh-negative individuals belong to genotype *rr* and are always homozygous; Rh-positive individuals may be either homozygous (genotype *RR*) or heterozygous (genotype *Rr*). Therefore, two Rh-negative parents can have only Rh-negative children. If one parent is Rh negative, and the other is Rh positive, the children will all be Rh positive if the Rh-positive parent is homozygous. If the Rh-positive parent is heterozygous, there is equal chance that the children may be Rh positive or Rh negative; or as it is usually stated, one-half of the children will be Rh positive and one-half will be Rh negative. When both parents are Rh positive, all the children will be Rh positive, except when the parents are both heterozygous, in which case one-fourth of the children will be Rh negative.¹¹

Rh-negative individuals may become sensitized to Rh antigen in one of two ways: (1) sensitization may result from a transfusion of Rh-positive blood, or (2) in women, sensitization may result from pregnancy with an Rh-positive fetus. Sensitization by either of these methods may result in a serious hemolytic reaction if transfusion with Rh-positive blood is given. Therefore, all Rh-negative women who are to be transfused must be given only Rh-negative blood.

In 1940 Levine and his co-workers¹² noted that sera of patients who had had repeated miscarriages or abortions contained atypical isoagglutinins related to the Rh factor. In 1941 Katzin found that the serum of the patient previously

described by Levine and Stetson¹³ agglutinated the same cells as the newly discovered antirhesus rabbit serum. Levine, Katzin, and Burnham¹⁴ called attention to the fact that a diagnosis of erythroblastosis fetalis had been made on some of the dead fetuses which came from the union of Rh-positive and Rh-negative people. Vogel¹⁵ noted that the majority of the mothers had Rh-negative blood. Burnham¹⁶ and Levine¹⁷ further called attention to the relationship of the Rh factor to erythroblastosis. The doctrine that Rh-positive fetal cells entering the maternal blood stimulate the formation of anti-Rh agglutinins is now accepted. Such agglutinins pass back to the fetus and then clump and destroy the fetal erythrocytes.

An excellent description of what takes place in the placenta itself was given by Pieri and Schwartz.¹⁸ They stated that the medium for the interchange of gases, water, and nourishment between mother and baby is the fragile wall of the placental villus, a trophoblastic projection of the chorion frondosum itself. Through an arteriole, each villus is supplied with fetal blood by a branch from one of the umbilical arteries, while a corresponding venule eventually returns the blood to the fetal circulation. The delicate placental villi are bathed in pools of maternal blood, in the intervillous spaces. The maternal blood is carried to these spaces by minute branches of the uterine artery, which are usually found in relation to the decidual septa, while corresponding veins return it eventually to branches of the uterine vein. Constant circulation is assisted by the uterine contractions which occur at intervals throughout every pregnancy. Normally, the blood of the child circulates inside the villus, while the maternal blood circulates outside this delicate structure. The relationship is so close that osmosis readily takes place through the villus wall. It has been estimated that if all the villi of a placenta at full term were placed end to end their combined length would exceed eleven miles.

That the placenta is extremely susceptible to the effects of tumors, trauma, and disease has long been known. This is not a surprising observation, in view of the complex structure and function of this organ, and of the fact that the more complex an organ the more delicate and vulnerable to injury it becomes.¹⁹ Careful scrutiny of the placenta²⁰ will reveal in nearly every instance the unmistakable evidences of one or many areas of old or recent pathologic alteration. Such scars, varying in size from pinhead to several cubic millimeters, have been designated by a confusion of terms, such as infarction, hepatization, placentitis, necroses, apoplexy, etc. Actually, each such scar represents merely the evidence of a previous placental injury. Since the most delicate portion of the placenta is the villus itself, this structure is the most susceptible to injury, either as a result of apoplexy, or of hemorrhagic infarction, or of direct trauma. Whatever

the causative factor, any violent break in the continuity of the vessels of one or more villi will result in hemorrhage of fetal blood cells into the maternal circulation. From here the fetal blood elements are carried into the uterine veins and

thence into the general circulation of the mother. Such a hemorrhage may be minute and apparently insignificant, or of considerable size.²¹ Either may produce most serious sequelae. Now, if the fetus' cells contain the Rh antigen (Rh positive), while those of the mother are without the antigen (Rh nega-

²¹Wiener, A. S.: Am. J. Obst. & Gynec. 56: 717, 1948.

tive), a variable degree of isoimmunization may result. The Rh-positive cells of the fetus stimulate within the Rh-negative mother formation of the specific Rh antibody (anti-Rh agglutinin).

If the mother now needs a transfusion, and Rh-positive donor blood is used, there follow hemolysis and agglutination of the donor's cells with resulting renal damage or even death, from the action of the isoantibodies (anti-Rh) on the incoming Rh-positive cells. Therefore, in all primary transfusions of Rh-negative pregnant or post-partum women use Rh-negative donors.

The Rh Factor in Erythroblastosis Fetalis

The Rh antibody, formed in the blood serum of the Rh-negative mother by virtue of the presence of an Rh-positive fetus (see above) is readily transmissible, as are many toxins and antitoxins, through the placental filter (the walls of the villi) into the circulation of the infant in utero. It is the action of this antibody upon the Rh-positive cells of the baby which produces the disease entity which in about 90 per cent of the cases is recognized as isohemolytic disease or erythroblastosis fetalis. In most of the remaining 10 per cent the disease apparently depends upon similar genetically related antigens (such as those designated as Hr or other blood group antigens), present in the baby's cells but absent in those of the mother.

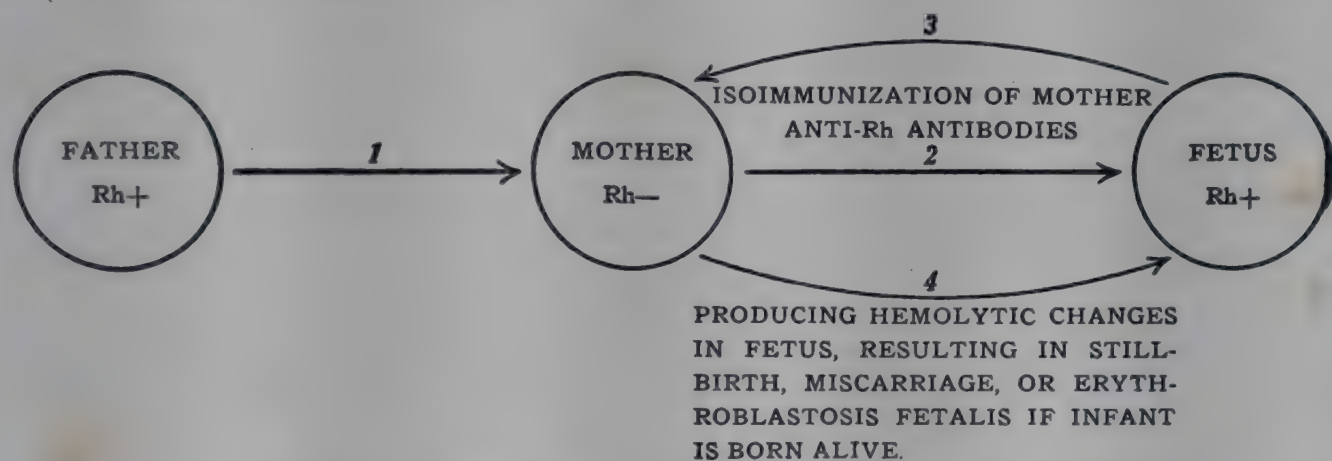

Fig. 244.—Diagram of the Rh phenomenon in pregnancy.

Fig. 244 illustrates what takes place in pregnancy when an Rh-negative woman is mated to an Rh-positive man. The Rh-positive fetus stimulates formation of Rh antibodies in the mother (isoimmunization). Anti-Rh agglutinins from the mother pass through an imperfect placental barrier, producing hemolytic changes in the fetus. This will result in miscarriage, stillbirth, or erythroblastosis fetalis if the infant is born alive.

While the mating of Rh-negative women with Rh-positive men occurs in one of ten marriages, congenital hemolytic disease affects only one in about two hundred and fifty newborn. This suggests that only about one in twenty-five Rh-negative women becomes sensitized when bearing an Rh-positive fetus, just as in sensitization by blood transfusion. The first-born is rarely affected, because it takes at least one pregnancy, and sometimes more, before a sufficient degree of sensitization develops. In most of the rare cases where the first-born was affected, a careful history has revealed that the women had previously received a transfusion of Rh-positive blood. This serves, according to Wiener,

to emphasize the importance of performing Rh tests before giving blood transfusions to women in the child-bearing age, as well as to young girls, because a transfusion of the wrong Rh type blood could ruin a woman's chances of having a normal child. Refer to pages 1038, 1043, and 1060 for a discussion of univalent antibodies.

Summary of Facts Relative to the Rh Factor

1. In Retransfusions.—

If the recipient is Rh negative and the donor is Rh positive, the Rh agglutinin in the donor's blood cells acts as an antigen and stimulates the formation of anti-Rh agglutinins in the patient's serum. The patient is now isoimmunized to the Rh factor.

If this patient is again transfused with Rh-positive blood cells, the Rh antibodies, formed as a result of the first transfusion, agglutinate or hemolyze the incoming donor cells, resulting in a transfusion reaction or death.

Therefore, since Rh-negative blood has no **Rh_o** factor, always use Rh-negative donor blood in retransfusions of Rh-negative patients.

2. In Primary Transfusions of Pregnant and Post-partum Women.—

If the mother is Rh negative and the father is Rh positive, the fetus will most likely be Rh positive. Through an imperfect placenta, the Rh-positive fetal blood seeps into the mother's circulation, causing the mother to form Rh antibodies (agglutinins) in her blood serum. She is now isoimmunized to the Rh factor.

If this isoimmunized woman were given a transfusion with Rh-positive blood, the Rh antibodies now present in her blood plasma react with the incoming donor blood cells and agglutinate them or hemolyze them, or both, resulting in a transfusion reaction or death.

Therefore, since Rh-negative blood cells contain no Rh agglutinin, always transfuse Rh-negative pregnant or post-partum women with Rh-negative blood.

3. In Erythroblastosis Fetalis.—

If the mother is Rh negative and the father is Rh positive, the fetus will frequently be Rh positive. Through an imperfect placenta, the Rh-positive blood seeps into the maternal circulation, stimulating the formation of Rh antibodies, and isoimmunizing the mother. Her blood serum now contains Rh antibodies. Through imperfections in the placenta,* some of the mother's blood, containing Rh agglutinins, now re-enters the fetal circulation, and agglutinates the Rh-positive cells. They also attack the hematopoietic system. As a result, the fetus is either expelled as an abortion, is macerated, is still-born, or, if born alive, develops erythroblastosis fetalis.

If the infant is transfused with Rh-positive blood cells, the Rh antibodies in the infant's blood (derived from the mother) react with the incoming Rh-positive donor blood cells and a reaction ensues.

Therefore, in all pregnancies where the mother is Rh negative and the father is Rh positive, be prepared for an erythroblastotic infant, and transfuse

*See discussion of univalent antibodies, page 1038.

the infant immediately upon birth with Rh-negative donor blood. If no Rh-negative donor is available, use the *washed* red cells of the Rh-negative mother. Washing the cells removes the anti-Rh antibodies. In emergencies, however, the mother's whole blood may be used.* See pages 1075 ff. for exsanguination transfusions.

Subtypes of Rh

It was found by Wiener** that the great majority of the human antisera gave reactions identical with those of the anti-rhesus rabbit sera, and such human antisera are now designated as standard anti-Rh or anti-**Rh_o**. The differences among human antisera were soon explained by the demonstration of two additional varieties of Rh agglutinins, one giving 70 per cent positive reactions and designated as anti-**rh'**, the other giving 30 per cent positive reactions and designated anti-**rh''**. If blood specimens are tested with all three antisera, anti-**Rh_o**, anti-**rh'**, and anti-**rh''**, eight distinct types of human blood can be identified instead of two, Rh positive and Rh negative, detected with the aid of standard human anti-Rh serum or animal anti-rhesus serum alone. As Wiener^{1, 2} has shown, the three Rh antisera detect three corresponding Rh factors, **Rh_o**, **rh'**, and **rh''**, which in combination give rise to at least five Rh agglutinogens instead of one; namely, **Rh_o**, **rh'**, **rh''**, **Rh₁** (or **Rh'_o**), and **Rh₂** (or **Rh''_o**). These five agglutinogens in combination determine the eight Rh types, which are hereditarily transmitted by means of at least six allelic genes, **R^o**, **r'**, **r''**, **R¹**, **R²**, and **r**.

The Rh blood types, like the blood groups and M and N types, exhibit striking differences in distribution in various races and have important applications in anthropology.³ Wiener has studied these facts in connection with races such as Chinese, Japanese, American Indians, Filipinos, Hawaiians, and Australian aborigines. In Negroes, he found the most striking finding was the high incidence of type **Rh_o**, which was about twenty times as frequent as in whites.

THE EIGHT Rh BLOOD TYPES*

DESIGNATION OF TYPES		REACTIONS WITH SERA			GENOTYPES
		ANTI- rh'	ANTI- rh''	anti- Rh_o	
Blood Containing Rh_o	Rh_o	-	-	+	R^oR^o and R^or
	Rh₁ (Rh'_o)	+	-	+	R¹R¹ , R¹r' , R¹r , R¹R^o , R^or'
	Rh₂ (Rh''_o)	-	+	+	R²R² , R²r'' , R²r , R²R^o , R^or''
	Rh₁Rh₂ (Rh'_oRh''_o) (Rh_z)	+	+	+	R¹R² , R¹r'' , R²r'
Blood Lacking Rh_o	rh	-	-	-	rr
	rh'	+	-	-	r'r' and r'r
	rh''	-	+	-	r''r'' and r''r
	rh'rh'' (rh_y)	+	+	-	r'r''

*This table does not contain the **Rh_o** variant or genes **r^y** and **R^z**.

The Hr Factor

Levine and Javert⁴ reported that they had detected in the serum of an Rh-positive mother of an erythroblastotic infant an antibody which had the property of agglutinating all Rh-negative bloods. Because of this property of the serum, the new agglutinable property detected by it was designated as Hr, and the corresponding agglutinin as anti-Hr. Levine reported that his anti-Hr serum gave about 30 per cent positive reactions and that all Rh-positive bloods not agglutinated by anti-rh' reacted with anti-Hr. On this basis he postulated that Hr and Rh were allelic, without further clarifying his hypothesis. He also asserted that Hr incompatibility must be considered as a possibility whenever an Rh-positive mother has an Rh-negative child, and that all type Rh₁Rh₂ individuals are Hr negative. These two statements, according to Wiener's observations and others, have been contradicted by subsequent findings. For instance, in 1943, Race and Taylor⁵ also detected in the serum of an Rh-positive mother of an erythroblastotic infant an agglutinin which reacted with all Rh-negative bloods, but differed from Levine and Javert's in that it gave 80 per cent positive reactions. As already pointed out by Wiener and associates,⁶ Race and Taylor's serum detected the same blood property as Levine and Javert's serum, the lower percentage of positive reactions obtained by Levine being due to the use of a weaker antiserum which missed bloods heterozygous for the Hr factor. As postulated by Race and associates,⁷ Hr is a blood factor present in the agglutinogens determined by genes R^2 , r'' , R^0 , and r , but absent from the agglutinogens determined by genes R^1 and r' and r^y and R^z . Wiener postulates that a single dose of a gene positive for Hr determines a weaker reaction with anti-Hr than a double dose of Hr-positive genes.^{5, 6}

The main clinical application of the Hr factor is as a presumptive test for homozygosity or heterozygosity of type Rh₁ fathers in families with erythroblastotic infants.⁵ The diagnosis is only presumptive because there are five genotypes in type Rh₁, while anti-Hr serum merely subdivides type Rh₁ into two parts.⁶ Hr'-negative individuals of type Rh₁ are almost surely homozygous for Rh₁, while hr'-positive individuals of type Rh₁ are almost always heterozygous and bear gene r .

The Rh-Hr Blood Types and Their Variants

As previously stated, Landsteiner and Wiener, in 1937, were able to immunize rabbits against the blood of rhesus monkeys. When they tested the antiserum produced in the rabbits against blood cells of human beings, they found that 85 per cent of those tested reacted with the anti-rhesus serum. They then postulated that 85 per cent of human beings contain in their serum an agglutininogen similar to that found naturally in rhesus monkeys. They called the factor in the cells "**Rh**," using the first two letters of the word "rhesus." Those whose blood contained this factor were designated as Rh

⁴Levine, P., Burnham, L., Katzin, E. M., and Vogel, P.: *Am. J. Obst. & Gynec.* 42: 925, 1941.

⁵Race, R. R., and Taylor, G. L.: *Nature* 152: 300, 1943.

⁷Race, R. R., Taylor, G. L., Cappell, D. F., and McFarlane, M. N.: *Nature* 153: 52, 1944.

positive, while those whose blood lacked the factor were called Rh negative. Later it was found that the blood serum of human beings who had been iso-immunized as a result of transfusions or of pregnancy contained the same antibody as the original anti-rhesus rabbit serum, and, in addition, two other related antibodies were found. Wiener then called the original antibody "anti-Rh₀," and the blood factor which stimulated its formation "Rh₀." The related Rh factors were designated "**rh**'" and "**rh**'," and the antisera "anti-**rh**'" and "anti-**rh**.'"

Since the **Rh**₀ factor is the most antigenic of the three, and since it causes more than 90 per cent of the cases of erythroblastosis fetalis and intragroup hemolytic transfusion reactions, it is written with a large letter *R*. The other two factors, **rh**' and **rh**'', are less antigenic, and are therefore written with the small letter *r*. Approximately 85 per cent of Caucasoids, 95 per cent of Negroids, and almost 100 per cent of Mongoloids have the Rh₀ factor in their blood.¹

The **Rh**₀ factor is found alone in 2.5 per cent of the population, and in combination with either **rh**' or **rh**'' or both in 82.5 per cent, so that 85 per cent of the population have the **Rh**₀ factor and 15 per cent lack it. The **rh**' factor is found alone in 1.0 per cent of the population, and combined with either **Rh**₀ or **rh**'' or both in approximately 70 per cent. The **rh**'' factor is found alone in only 0.5 per cent of people, but in combination with either **Rh**₀ or **rh**' or both in 30 per cent. Approximately 87 per cent of the population, therefore, are Rh positive, and 13 per cent type rh. The Rh factors do not represent separate structures on the red cell envelope, but are attributes of complex structures, the Rh agglutinogens, and each is characterized by one or more Rh factors. The **rh**^w factor, for example, occurs only in association with factor **rh**'.

By combination of the three principal Rh factors, the following Rh agglutinogens have been identified (the types are described in Table 102):

<i>Rh Agglutinogen</i>	<i>Factors Present</i>
Rh ₀	Rh ₀
Rh ₀ ' = Rh ₁	Rh ₀ and rh '
Rh ₀ '' = Rh ₂	Rh ₀ and rh ''
Rh ₀ ''' = Rh ₃ (Rh ₁ Rh ₂)	Rh ₀ , rh ', and rh ''
rh	No Rh factors
rh'	rh '
rh''	rh ''
rh _y (rh'rh'')	rh ' and rh ''

One must distinguish between "blood factors" and "agglutinogens." An agglutinogen is a definite hereditary substance of unknown chemical composition present on the red cell envelope; red cells have a number of such agglutinogens. Blood factors are attributes or properties of the structure called an agglutinogen. Each agglutinogen has multiple blood factors which are the serologic attributes by which the agglutinogen can be identified. Agglutinogens are antigenic and capable of inducing antibody formation in the serum of susceptible subjects, specific for one or more of its various blood factors; such sera are used for diagnostic purposes. The convention has been adopted

¹Wiener, A. S.: *An Rh-Hr Syllabus*, New York, 1954, Grune & Stratton.

to print symbols of blood factors and their specific antisera in bold-face type; symbols for agglutinogens and phenotypes are printed in regular type; genes and genotypes are printed in italics.

Adequate methods must be used to determine Rh factors and to identify Rh antibodies and other atypical antibodies.

Since the **Rh₀** factor is the most antigenic of the Rh-Hr factors, and therefore the one to which most human beings respond most readily, it is clinically the most important. No patient whose blood lacks the **Rh₀** factor should be transfused with blood that contains it. Thus, recipients who are type rh', type rh'', or type rh₀ must be given only Rh-negative blood, since they lack the **Rh₀** factor and can be isoimmunized against it if given blood containing **Rh₀**. On the other hand, if a donor belongs to type rh', type rh'', or type rh₀, such blood must *not* be given to Rh-negative recipients, for such recipients can produce anti-rh' or anti-rh'' antibodies, so that if the donor belongs to any of these three types, such blood should be given only to Rh-positive individuals.

The **Hr** factors are factors reciprocally related to the Rh factors, and can be found only when the corresponding Rh factor is absent. The symbol "Hr" was first suggested by Levine to indicate the relationship between Rh and Hr. Antisera for factor hr' and factor hr'' have been found, but no anti-Hr₀ serum has as yet been discovered. The hr' factor occurs in 80 per cent of the population, and the hr'' in 98 per cent, so that only 20 per cent lack the hr' factor and 2 per cent lack the hr'' factor. The Hr factors are much weaker antigens than the **Rh₀** factor. This explains the relative infrequency of transfusion reactions and cases of erythroblastosis fetalis due to the Hr factors. Nevertheless, they are important and must not be ignored.

Since the Hr factors are counterparts of the Rh factors, those who are rh' negative are always hr' positive, and those who are rh'' negative are hr'' positive,* and vice versa.

Antisera for the Rh-Hr types now available are anti-**Rh₀**, anti-rh', anti-rh'', anti-rh₀, anti-hr', and anti-hr''. In addition, a new antibody has recently been found, called "anti-hr." This is specific for a factor in the agglutinogens determined by the *R*⁺ and *r* genes, but does not increase the number of phenotypes.† (See page 1053.) There is also an anti-rh⁺ serum, which reacts with 4 to 8 per cent of all bloods. Each antiserum reacts with its specific blood factor to cause agglutination.

With the three basic anti-Rh sera, eight Rh types are distinguishable. Table 102.

Wiener selected the names Rh₀ and Rh₁ for the sake of simplicity and also to indicate that the blood factors in such bloods are usually combined to form a unit agglutinogen inherited by a corresponding gene.

If a fourth antiserum is used, namely, anti-rh⁺, types rh', Rh₀, rh₀, and Rh₁ can be subdivided into those which give negative results and those

*Rare exceptions to this rule have recently been described (Wiener, A. S., Gordon, E. B., and Cohen, A., *Ann. N. Y. Acad. Sci.*, 4: 144, 1947; Rosenfield, R., et al., *Proc. M. J. 1: 912, 1947; Wiener, A. S., *Brit. M. J.* 1: 1091, 1947).*

TABLE 102.—REACTIONS WITH ANTISERA

ANTI rh'	ANTI rh''	ANTI Rh ₀	TYPE	Rh FACTORS PRESENT
-	-	-	rh, or triple Rh negative	None
+	-	-	rh'	rh'
-	+	-	rh''	rh''
+	+	-	rh, rh'	rh', rh''
-	-	+	Rh ₀	Rh ₀
+	-	+	Rh ₀ , rh'	Rh ₀ , rh'
-	+	+	Rh ₀ , rh''	Rh ₀ , rh''
+	+	+	Rh ₀	Rh ₀ , rh', rh''

which give positive results, and the latter are named rh'', Rh'', rh''rh'' and rh''Rh₀. (Factor rh'' occurs only in bloods containing rh').

There are two main Hr antisera, anti-hr' and anti-hr''. If an Rh factor is absent, the corresponding Hr factor is present and vice versa. Exceptions to this are extremely rare. If, however, an Rh factor is present, the corresponding Hr factor may or may not be present. Thus, when the three anti-Rh sera and the two anti-Hr sera are used simultaneously, 18 Rh-Hr types are determined. If a third Hr antiserum, anti-Hr₀, were found, the number of Rh-Hr types would be increased to 27. Sensitization by hr' and hr'' factors can cause clinical complications indistinguishable from those caused by the Rh factor. Ideally, a complete Rh-Hr typing should be made of both donor and recipient in each transfusion, and only type-specific blood transfused, but at present this is not possible.

The Rh₀ factor is the variant of the Rh factor, and is called the "Rh₀ variant." It must be tested for if the standard Rh factor is found to be absent.

If all 5 testing sera are used to test unknown blood, one no longer is justified in saying merely "Rh positive" or "Rh negative." The designations of types should be made according to Table 103.

TABLE 103

ANTISERA USED					DESIGNATION OF TYPES
ANTI Rh ₀	ANTI rh'	ANTI rh''	ANTI hr'	ANTI hr''	
-	-	-	-	-	Rh ₀
-	-	-	-	+	rh'rh'

-	-	-	+	+	Rh ₀ , Rh ₀
-	-	-	+	+	Rh ₀ , Rh ₀

The Nature of the Rh-Hr Antibodies

There are two distinct varieties of Rh-Hr antibodies of any given specificity, formed as a result of isoimmunization with the Rh agglutininogen, and each reacts best in the laboratory under different test conditions.

The first variety, called "agglutinins" or "bivalent antibodies," or "complete" or "early immune" antibodies, clumps specific cells when these are suspended either in saline or in high colloid medium, or if these same cells are enzyme-treated and suspended in saline.

The second variety, called "glutinins" or "blocking" or "univalent" or "incomplete" or "hyperimmune" antibodies, does not produce visible clumping of specific cells when these are suspended in saline, but simply combines with the factor for which it is specific, and "coats" the cells or "blocks" the reaction. (Coating of the cells can be detected by the antiglobulin or Coombs test.) This variety of antibody will clump specific cells by its combined action with conglutinin normally present in serum, or by added colloidal substitutes such as acacia or gelatin (conglutination), and also when specific cells have been enzyme-treated and then suspended in saline and then followed by the antiglobulin test (Unger test).

There is evidence that there may be a third variety of antibody which "coats" cells but lacks the capacity to clump them when they are suspended either in saline or in high colloid medium, but this coating may be detected by the antiglobulin method.

Wiener¹ described the difference between the two varieties of antibodies and their reaction in vitro as follows:

Anti-Rh agglutinins (bivalent) + Rh-positive cells = Rh agglutination.

Anti-Rh glutinins (univalent, or blocking antibodies) + Rh-positive cells + X protein = Rh conglutination. The third component listed here, X protein, is a normal component of blood serum. It is adsorbed onto the specifically sensitized red cells, causing them to stick together. This X protein is distinct from complement. It resists heating at 60° C. and is a colloidal constituent or conglutinin in the plasma, a large molecular complex of albumin, globulin, fibrinogen, and phospholipid. X protein, although heat-resistant, dissociates readily into its constituent smaller molecules of albumin and globulin upon dilution of the plasma with water. Use of saline, to suspend cells or to dilute serum, either partially or completely dissociates the X protein. Thus, in order to carry out conglutination tests, any crystalline solution must be strictly avoided.

Univalent or blocking antibodies are very important. They tend to appear usually late in the course of immunization, are relatively heat-resistant, and readily pass through the intact placenta (Wiener).

Bivalent antibodies are usually produced early in the course of immunization, are relatively thermolabile, and are effectively held back by the intact placental barrier.

Other Blood Systems

The Lewis System.—Two related Lewis factors have been found, designated **Le^a** and **Le^b**, respectively. Adults who are **Le^a**-positive almost invari-

¹J. Lab. & Clin. Med. 30: 662, 1945.

ably are nonsecretors of the A-B-O group substances, while **Le^a**-negative persons are secretors (Grubb*). Since great difficulty has been encountered in obtaining potent and specific reagents for detection of the Lewis factors, many aspects of this system are still unclear.¹

Kell-Cellano Types (K-k).—Antibodies for a blood property present in approximately 10 per cent of Caucasoids have been found in occasional sera from mothers of erythroblastotic babies, and also in sera of persons who have had hemolytic transfusion reactions.² The symbol "**K**" was selected for this factor after the patient, Kell, in whose serum the antibody was first detected.

More recently an antibody was encountered in the serum of a mother of an erythroblastotic baby which gives reactions reciprocally related to the Kell factor. This factor was designated "Cellano," after the patient.³ It has an incidence of 99.8 per cent among Caucasoids. It has been assigned the symbol "**k**" to indicate its reciprocal relationship to the Kell factor. When tests are made with both anti-**K** and anti-**k** sera, three types can be differentiated: type KK in 0.2 per cent; type Kk in 8.6 per cent; and type kk in 91.2 per cent.

Most of the anti-**K** sera must be used with the agglutination and antiglobulin methods. Limited quantities of anti-**K** serum are commercially available.

Duffy or Fy^a Factor.—The so-called *Duffy*, or **Fy^a** factor has been the occasional cause of hemolysis in isosensitized patients. These reactions have been serious, and therefore the factor is important. They are demonstrable only by the antiglobulin technic.

Blood Factors S and s, of the M-N-S Group.—For a long time, the M-N types were considered to constitute a simple system of only three types, M, N, and MN, but with the development of new methods for detecting immune iso-antibodies, it was demonstrated that the M-N system is far more complicated than at first believed.

In 1947, Walsh and Montgomery⁴ found in the serum of a mother of an erythroblastotic baby not only an Rh antibody, but also a second antibody. This gave reactions related to the M-N system. The new agglutinin was designated by the symbol "**S**" and the corresponding antibody as "anti-**S**."

In 1951, Levine and associates⁵ detected an antibody in the serum of a mother of an erythroblastotic baby which gave reactions reciprocally related to the agglutinin S. The new agglutinin was designated "**s**," and the corresponding antibody "anti-**s**."

Discovery of anti-**s** serum has increased the interest and importance of the M-N-S system, because when all four antisera are available, it becomes possible to differentiate as many as 9 phenotypes corresponding to the 10 theoretically possible genotypes.

Only a limited quantity of the antisera is available at present.

Blood Factor U.—In 1953, Wiener, Unger, and Gordon⁶ found in the serum of a Negroid woman an abnormal antibody which strongly agglutinated the cells of the two donors whose blood had been used in transfusing her.

This was a case of a fatal hemolytic reaction in a woman who entered the hospital with a diagnosis of bleeding peptic ulcer. She was given a transfusion, but this was discontinued after 100 c.c. of blood had been administered, because of a reaction consisting of chills and fever. Another blood transfusion was carried out a week later. The patient died shortly thereafter.

The antibody found in the serum was of high titer and avidity. At body temperature, the titer was approximately 400 units, and at refrigerator temperature only 40 units. This antibody had the property of an immune iso-antibody in contradistinction to naturally occurring antibodies such as anti-**A**, anti-**B**, and anti-**P**. It was active by the ordinary agglutination method in saline medium. The blood factor was not affected by proteolytic enzymes.

Tests made on a short series of blood specimens showed them all incompatible with the patient's serum; therefore the factor in question has a high frequency in the population. It apparently is not related to any known blood factor, and has been given the name "**U**."

No Caucasoids out of 690 tested have been found to give a negative reaction to the antisera, and out of 425 Negroids, only four were negatively reacting.

* * * * *

With the increase in the number of transfusions and the discovery of so many blood factors not heretofore known, it has become increasingly evident that blood grouping is a highly specialized field, and these delicate tests must be carried out with precision by specially trained persons if fatal hemolytic reactions are to be avoided.

Summary of the Blood Groups in Man and Their Role in Transfusion

Most of the newly described factors found in blood have been discovered as a result of a hemolytic transfusion reaction or the birth of an erythroblastic infant, which could not be explained on the basis of Rh_0 sensitization. Application of the tests for univalent antibodies to a study of such cases may reveal the presence of an unusual antibody in the patient's serum, and thus most of the newer factors are potentially important clinically. However, it is not necessary to test all recipients of blood transfusions or every pregnant woman for all of these factors. Observations have shown that while the majority of Rh-negative individuals injected with Rh-positive blood eventually become sensitized, this is not true for other blood factors. For example, injections of hr' -positive blood into hr' -negative individuals experimentally seldom stimulate production of specific antibodies; this indicates that hr' is far less antigenic than the Rh_0 factor. The same appears to be true for blood factors rh' , rh'' , rh^w , hr'' , **F**, **K**, **S**, etc. It is therefore adequate to test prospective recipients of blood transfusion for the A-B-O groups and the Rh_0 factor and to rely on proper cross-matching tests and tests for sensitization to detect incom-

⁶Wiener, Unger and Gordon.: J.A.M.A. 153: 1444, 1953.

TABLE 104.—BLOOD GROUPS IN MAN: ROLE IN BLOOD TRANSFUSION¹

SYSTEM	BLOOD FACTORS	NUMBER OF IDENTIFIABLE TYPES		ISOANTIBODIES		ROLE IN CAUSING TRANSFUSION HEMOLYSIS	
		NATURAL	IMMUNE	Common	Most important	Common	Most important
A-B-O	A, B, C, O, and variants such as A ₁ , A ₂ , A ₃ , A _{1,2} and A ₃ , etc.	6 major groups and subgroups—O, A ₁ , A ₂ , B, A ₁ B, A ₂ B; also rarer subgroups A ₃ , A ₃ B, etc.	Regularly present except during neonatal period	Common	Has caused hemolysis in rare cases	Most frequent cause of intragroup transfusion hemolysis	Most frequent cause of intragroup transfusion hemolysis

Kidd (Jk)	J and j	2 major types, because anti-j serum is not available	None reported	Few cases	Rare cause of hemolysis	Rare cause of hemolysis	Rare cause of hemolysis
“Private” blood types*							
Rare blood factors	Leavy, Gr (Graydon), Mia (Miltenberger), Becker, Bea (Berrens), Ca (Cavaliere), Wra	Positively reacting bloods are very rare	None reported	Very rare	Very rare cause of hemolysis	Very rare cause of hemolysis	Very rare cause of hemolysis
Factors with almost universal distribution†	Tja and U	Negatively reacting bloods are very rare	None reported	1 case anti-U; 8 cases anti-Tja	Very rare cause of transfusion hemolysis	Very rare cause of transfusion hemolysis	Very rare cause of transfusion hemolysis

*In the case of the rare blood factors, other individuals possessing such factors are most easily found by testing relatives of the proband, the person in whose blood the factor was first found. Similarly, individuals, lacking factors of almost universal distribution are to be found most readily among relatives of the proband. The hereditary nature of the blood factors, in general, is most noticeable in the case of very rare blood types, and Levine has, therefore, designated them as “private” blood types to indicate their restriction to certain rare families.

†Factor k of the K-k blood types could also be included under this classification.

¹From Wiener: New York J. Med. 54: 3071, 1954.

patibilities with regard to the other human blood factors. Such incompatibilities are rare, and will be found only in individuals who have had previous transfusions or pregnancies which could have sensitized them.

Some of these factors are demonstrable only by the antiglobulin method. Table 104 is a résumé of the blood groups and their role in transfusion.

Rh-Hr Glossary*

Antigen: Any substance which when introduced into the body, usually by a parenteral route, stimulates the formation of specific reacting substances.

Antibodies: Specifically reacting substances, believed to be globulins in chemical structure, produced by the body in response to the introduction of an antigen.

Red Cell Antibodies: Substances occurring in blood serum which react with their specific antigen or agglutinin, which are found on the surface of red cells. Some antibodies clump cells, some coat cells, some lyse cells, etc.

Agglutinin: A substance on the surface of red blood cells which, in combination with its specific antibody (agglutinin), results in clumping of the cells. Agglutinogens are named for the most important blood factor or factors which characterize them. For example, agglutinin A is named for blood factor **A**, although it shares factor **C** with agglutinin B. (Agglutinin A also has a factor **F_A**, which it shares with sheep cells.)

Anti-rhesus serum: In the narrow sense, antiserum prepared in rabbits, guinea pigs, goats, and other animals in response to the injection of blood of rhesus monkeys. Thus, the term applies to sera like the original experimental serum of Landsteiner and Wiener, which clumps the bloods of 85% of all Caucasoids. In the broad sense, the term has been applied to include also all related Rh and Hr antisera of human origin.

Isoimmunization; isosensitization: Production of antibodies by an individual of a species in response to stimulation by an antigen derived from a different member of the same species. (See pages 1024 ff.)

Rhesus factors; Rh factors; Rh agglutinogens; Rh antigens: Structures on the surface of red blood cells responsible for the reactions with Rh antisera. Study of anti-Rh sera of human origin show that there are a variety of factors related to the original rhesus factor of Landsteiner and Wiener. The one corresponding to the original factor is designated **Rh₀**. Reciprocally related factors are termed **Hr factors**. There are four Rh factors: **Rh₀**, **rh'**, **rh''**, and **rh^w**. Three Hr factors have been found: **hr'**, **hr''**, and **hr**. There are also minor variants of the Rh-Hr factors.

Rhesus antibodies, Rh antibodies: The specific substances responsible for the reactions produced by anti-rhesus sera. The anti-rhesus (anti-Rh) sera prepared by immunizing animals with rhesus blood give parallel reactions with human bloods. The anti-rhesus (anti-Rh) sera of human origin are of 7 principal varieties. (1) Rh antibodies: anti-**Rh₀**, anti-**rh'**, anti-**rh''**, and anti-**rh^w**; (2) Hr antibodies: anti-**hr'**, anti-**hr''**, and anti-**hr**.

Rh₀ factor; standard Rh factor: This is the original Rh blood factor which corresponds to the original rhesus factor of Landsteiner and Wiener, and is present in the blood of approximately 85% of Caucasoids, 95% of Negroids, and almost 100% of Mongoloids. It is the most antigenic of the Rh-Hr factors, and therefore the most important clinically. More than 90% of cases of erythroblastosis fetalis and intra-group hemolytic transfusion reactions are due to this factor. When one speaks of the Rh factor, it usually is assumed that the **Rh₀** factor is meant. The symbol for the factor **Rh₀** is written with a large "R" to indicate that this is by far the most antigenic of the factors.

*Wiener, A. S.: Lab. Digest 12: 12, 1949; 14: 6, 1950; Wiener, A. S.: An Rh-Hr Syllabus, New York, 1954, Grune & Stratton.

Anti-Rh₀ serum; standard anti-Rh serum: Serum specific for the Rh₀ factor. Only anti-Rh₀ serum of human origin is used for diagnostic purposes, since anti-rhesus immune animal serum clumps all blood specimens from newborn infants.

Rh testing: Classifying human blood by tests with anti-Rh₀ serum alone. This divides all bloods into two types, Rh positive and Rh negative, or, strictly speaking, Rh₀ positive and Rh₀ negative.

TABLE 105.—SCHEME OF THE EIGHT Rh BLOOD TYPES

BLOOD CONTAINING FACTOR Rh ₀ (Rh ₀ POSITIVE)				BLOOD NOT CONTAINING FACTOR Rh ₀ (Rh ₀ NEGATIVE)			
DESIGNATION OF TYPES*	REACTIONS WITH SERA			DESIGNATION OF TYPES*	REACTIONS WITH SERA		
	ANTI-rh'	ANTI-rh''	ANTI-Rh ₀		ANTI-rh'	ANTI-rh''	ANTI-Rh ₀
Rh ₀	—	—	+	rh	—	—	—
Rh ₁	+	—	+	rh'	+	—	—
Rh ₂	—	+	+	rh''	—	+	—
Rh ₃ (Rh ₁ Rh ₂)	+	+	+	rh _y (rh'rh'')	+	+	—

*Type Rh₁ contains the two factors Rh₀ and rh', the name Rh₁ being short for Rh₀rh'; similarly Rh₂ is short for Rh₀rh'' and Rh₃Rh₂ is short Rh₀Rh₀rh''.

Hr factors: Factors of Rh-Hr agglutinogens, which are responsible for reactions with Hr antisera. They are reciprocally related to the Rh factors, for which reason Levine first used the symbol "Hr" to indicate this relationship.

Hr sensitization: The process of becoming sensitized to one or more of the Hr factors. When the Hr factor is not specified, it is usually the hr' factor which is intended, since this is by far the most antigenic, and the most important clinically.

Hr testing: Examination of the blood with Hr antiserum. When the exact serum is not indicated, it is usually anti-hr' serum which is intended.

Rh typing: Classification of blood within one of the eight Rh types with the aid of all three Rh antisera (see Table 111): anti-Rh₀, anti-rh', and anti-rh''. There are four Rh₀-positive types and four Rh₀-negative types. For blood transfusions to all Rh-negative recipients, only type rh (Rh negative by the use of all three Rh antisera) should be given, to avoid isoimmunization due to injection of blood containing rh' or rh'' factors. All recipients who belong to types rh' or rh'' must be given Rh-negative blood (type rh); since they lack the most antigenic of the Rh factors, Rh₀, they must not receive Rh₀-positive blood in a transfusion. All donors who are Rh₀-negative but rh'- or rh''-positive must give their blood only to Rh-positive individuals.

Univalent antibodies: One form in which antibodies of any given specificity may occur. Such antibodies tend to appear usually late in the course of immunization, are relatively thermostable, and readily pass through the intact placenta. In saline media, univalent Rh₀ antibodies combine with and coat Rh-positive cells without clumping them. In protein media or in the presence of high-molecular colloids, univalent Rh antibodies clump cells containing the corresponding specific blood factor.

Bivalent antibodies: Another form in which antibodies of a given specificity may occur. Such antibodies usually are produced early in the course of immunization, are relatively thermolabile, and are effectively held back by the intact placental barrier. In saline as well as colloidal media, they are capable of directly clumping cells possessing the corresponding specific antigen.

The differences between the bivalent and the univalent antibodies are summarized in Table 106.

Agglutination: Specific clumping of cells produced by bivalent antibodies.

Conglutination: Specific clumping of cells produced by the combined action of univalent antibodies and congrutinin.

Conglutinin: A colloidal aggregate of serum proteins which is adsorbed by cells that have been sensitized by their specific univalent antibody, but not by cells that have not been sensitized, and after adsorption, causes the cells to stick together. Conglutinin is relatively thermostable, but is sensitive to dilution with crystalline solutions, which causes it to dissociate into its constituent molecules. It is related to complement.

Conglutinin substitutes: Surface colloids, such as acacia, gelatin, dextran, and PVP, of complex molecular structure which can take the place of plasma in the conglutination test. Their ability to produce conglutination is due to their cohesive and adhesive properties, but they have the disadvantage of causing cells not coated by glutinin to clump weakly, an undesirable quality not exhibited by natural or fortified conglutinin, and therefore it is dangerous to use these substitutes.

Fortified conglutinin: Conglutinin which has been improved by the addition of the optimal amounts of albumin. Appropriate amounts (one-fourth to one-third its volume) of 30% albumin mixed with plasma contribute to the colloidal aggregates of protein in the plasma and thus enhance the conglutinin effect.

Rh antisera, anti-Rh sera, anti-rhesus sera: Sera containing Rh or Hr antibodies, or both. These antibodies may occur singly, such as anti-Rh₀, anti-rh', anti-rh'', anti-rh^w, anti-hr, anti-hr', and anti-hr'', or in combinations, such as anti-Rh₀', anti-Rh₀'', anti-Rh₀''' anti-rh'', hr', and anti-rh', hr''.

Rh agglutinating serum: Serum containing Rh antibodies predominately of the bivalent variety. Such antisera usually give best results by the so-called tube agglutination method in which dilute saline suspensions of red cells are mixed with the testing serum in small tubes, and the reactions read after incubation at body temperature for 60 to 120 minutes.

Rh conglutinating serum: Serum containing Rh antibodies predominately of the univalent variety. Such sera give best results by a variety of technics utilizing the principles of conglutination. For example, in the slide method a drop of serum is mixed with a drop of the whole, undiluted, oxalated blood being tested, and the reaction read with the naked eye after the slide has been tilted back and forth for a minute or two over a warmed viewing box. Tube technics may also be used, for example, by using diluted suspensions of cells in plasma or albumin instead of saline. It is possible that all Rh antisera contain a mixture of both univalent and bivalent antibodies. If the univalent antibodies predominate, the antiserum must be used by a conglutination method; if bivalent antibodies predominate, the tube agglutination test may be used. If antiserum containing a suitably balanced mixture of Rh₀ agglutinating and blocking antibodies is titrated in saline medium, a prozone may occur.

Rh sensitization; Rh immunization: The act of becoming sensitized to the Rh factor. This may occur in an Rh-negative individual as a result of a transfusion or an injection of Rh-positive blood or as the result of a pregnancy with an Rh-positive fetus. Injections of small doses (2 c.c.) of Rh-positive blood into Rh-negative individuals, at four-month intervals, cause more than 40% of subjects to become immunized (for preparation of anti-Rh serum). When injections are continued, more than 75% of Rh-negative persons can be immunized. Clinically, two widely spaced transfusions of Rh-positive blood into Rh-negative persons are more likely to lead to Rh sensitization than multiple transfusions in a short space of time. Fetal blood enters the maternal circulation during the course of approximately one out of three normal pregnancies, and one out of three deliveries. Once a person has been sensitized to the Rh factor, he remains so for the remainder of his life, although the titer gradually becomes weaker. When this occurs, a small injection of Rh-positive blood will stimulate a pronounced and sustained rise in antibody titer.

Rh agglutination test: A test to detect Rh antibodies of the bivalent type. When applied to sera from Rh-negative individuals being tested for Rh sensitization, a drop of the patient's whole serum is mixed with a drop of 2% saline suspension of the three types of Rh-positive red cells (group O) and the reactions are read after the mixture has been incubated at body temperature for 1 hour. See Fig. 245.

Rh blocking test: A test to detect Rh antibodies of the univalent variety. This test is also known as the indirect test for univalent Rh antibodies. The patient's whole serum or diluted serum is first mixed with a 2% saline suspension of Rh-positive red cells as in the agglutination test. If no clumping occurs a drop of good anti-Rh₀ agglutinating serum of moderate titer is added and the mixture incubated

1 or 2 hours at body temperature. See Fig. 245. The failure of clumping to occur despite the addition of anti-Rh₀ agglutinating serum, or a distinct weakening of the reaction, indicates the presence of Rh₀ blocking antibodies.

COMPARISON OF Rh AGGLUTINATION AND BLOCKING REACTION

(Test in Saline Media)

Rh CONGLUTINATION REACTION

(Tests in Plasma or Serum Media)

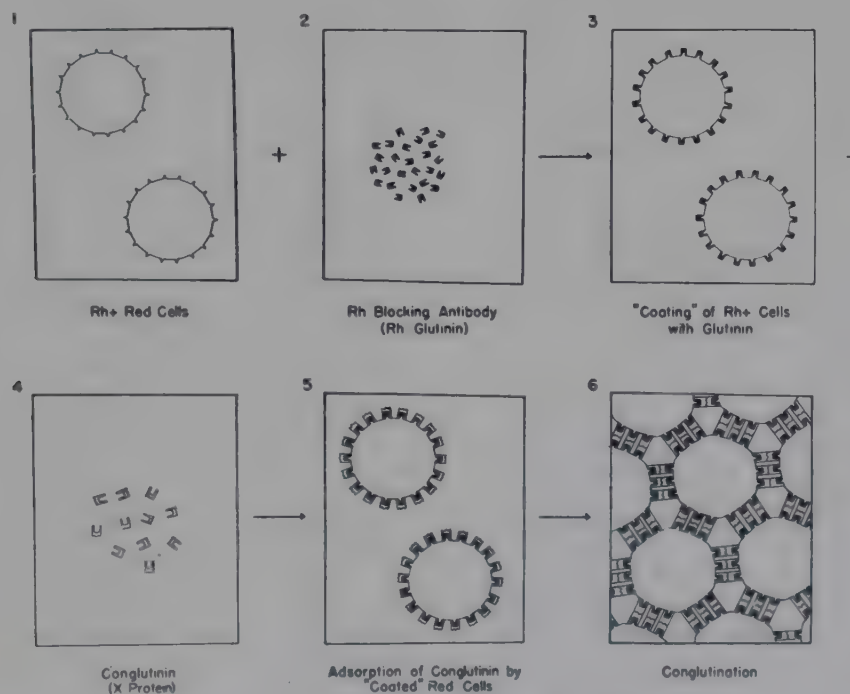

Fig. 246.—(Courtesy A. S. Wiener: Lab. Digest 14: No. 6, 1950.)

Rh conglutination test: Another test for Rh antibodies of the univalent variety, also known as the direct test for univalent Rh antibodies. When applied to the patient's serum, the initial stage of the test is the same as for the agglutination or blocking tests. After the red cells have sedimented, however, the supernatant fluid is removed as completely as possible and replaced by a drop of albumin-plasma mixture

(3 or 4 parts pooled plasma and 1 part 30% bovine albumin). The cells are re-suspended and the reactions read after another period of incubation. The technic can be carried out in a tube in a single step, by using test cells suspended in 20% albumin solution. The conglutination test, when properly performed, is 5 to 40 times as sensitive as the blocking test for detecting univalent antibodies. Other modifications of the test have also been devised. See Fig. 246.

Antiglobulin test, "developing" test, indirect Coombs test for Rh antibodies: Another method for testing for univalent Rh antibodies. The test depends on the fact that the univalent antibodies coating the red cells are human serum globulin. A precipitating rabbit antiserum, prepared by injecting human serum or purified human serum globulin into rabbits (Coombs serum, commercially available), is first absorbed with pooled washed human red cells to remove heteroagglutinins, and is then diluted to optimum strength. The patient's whole or diluted serum is allowed to react with a saline suspension of Rh-positive cells (group O). The sensitized cells are then washed three times with a large volume of saline to remove the supernatant human serum proteins as completely as possible. A drop of Coombs serum is then added, and the mixture centrifuged at 500 r.p.m. for 2 minutes. If the cells are then clumped, this indicates that they have been sensitized by univalent antibodies; failure to clump indicates the absence of sensitization. See Fig. 247.

ANTIGLOBULIN METHOD OF TESTING FOR UNIVALENT Rh ANTIBODIES

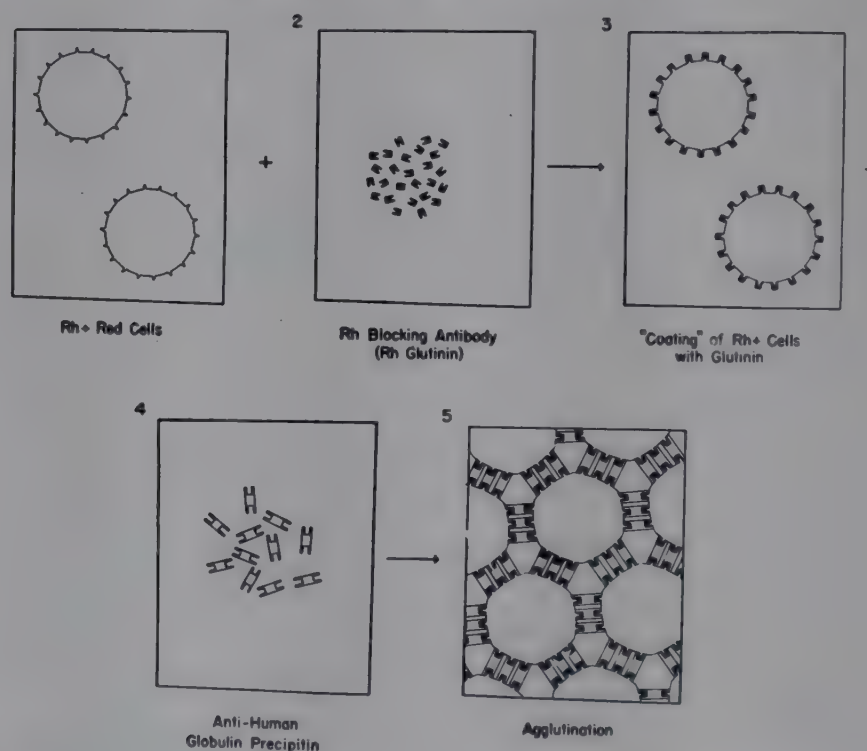

Fig. 247.—(Courtesy A. S. Wiener: Lab. Digest 14: No. 6, 1950.)

Rh antibody tests with enzyme-treated cells: If group O, Rh-positive red cells are washed three times to remove enzyme inhibitor and then treated with proteolytic enzymes like trypsin or papain, they become agglutinable by antisera containing the corresponding univalent Rh-Hr antibody. This test detects the same antibody as the blocking test, the conglutination test, and the antiglobulin test. The test with enzyme-treated cells equals the other tests in specificity and exceeds them in sensitivity. If the sensitivity of the blocking test can be rated as 1, then the sensitivity of the albumin-plasma conglutination test could be rated as approximately 30, the sensitivity of the anti-globulin test as approximately 50, while the sensitivity of tests done with enzyme-treated cells could be rated as approximately 100. The reactions obtainable in the tests with enzyme-treated cells are indicated diagrammatically in Fig. 248.

Titration: Determining the antibody in an antiserum. Unlike chemical titrations, serologic titrations have a large intrinsic error, so that variations up to 100% or 200% are not unusual even in the hands of experts. In the usual technics, the test cells are mixed with progressively doubled dilutions of the serum being examined in a series of tubes, and the highest dilution giving a distinct positive reaction determined.

Titer of a serum: The amount of specific antibody in an antiserum; the strength of a serum. This is usually expressed in units, which are best calculated by taking the reciprocal of the highest dilution giving a so-called one-plus reaction. When determining the titer of a testing serum, the method of titration used should correspond to the method used in the actual tests, if the titer value is to have any significance. The literature contains many reports of fantastically high titers, running into the millions, due in part to "carrying over" and in part to selecting vague reactions as the end point. To avoid such blunders, and in view of the intrinsic inaccuracy of the method, one should calculate the titer values by taking the average of many tests done on different days with many different test cells.

CLUMPING OF ENZYME-TREATED Rh-POSITIVE CELLS BY UNIVALENT Rh ANTIBODIES

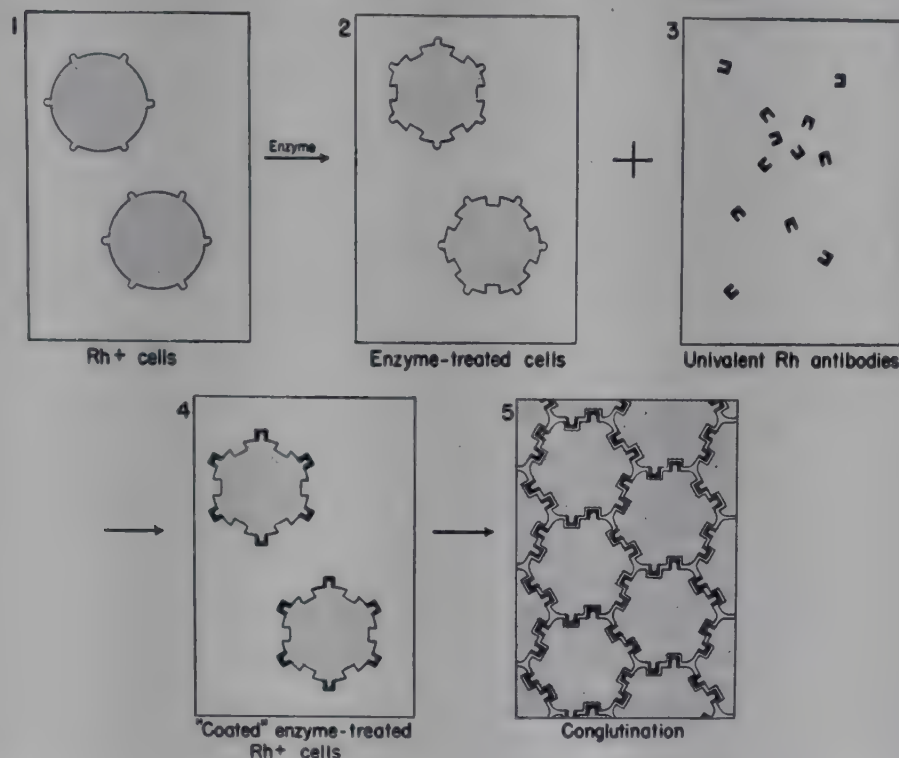

Fig. 248.—(Courtesy A. S. Wiener: Lab. Digest 14: No. 6, 1950.)

Rh₀ blocking serum: An Rh₀ antiserum containing univalent Rh antibodies of sufficiently high titer to give a distinct blocking reaction. Depending on the method used, an Rh₀ antiserum must contain a minimum of 5 to 40 units of univalent antibody, as determined by the conglutination method, in order to give a distinct blocking reaction.

Phenotypes: The characteristics of individuals of a species as determined by direct observation, measurement, chemical or serologic testing, etc. Thus, the characteristics, blue eyes, tall, short, harelip, hemophilic, group O, knock-knees, Rh₁Rh₂, etc., all represent phenotypic characteristics. The phenotype may be partly or wholly genetically determined, or may be entirely determined by the environmental influences; e.g., the color of the hair is usually genetically determined, but in some individuals it may merely be the result of beauty treatment.

Rh typing: Classification of individuals within one of the eight Rh types with the aid of anti-Rh₀, anti-rh', and anti-rh'' sera. Note the distinction between "Rh-typing" and "Rh testing."

Genotypes: The constitutional make-up of an individual, as determined by heredity. The genotype is transmitted through the germ cells by means of their chromosomes, although there is evidence also, in rare exceptional cases, of cytoplasmic inheritance. According to the gene theory, each of the 24 pairs of chromosomes contains numerous genes arranged in linear order. Every individual has a pair of each kind of genes, one derived from the maternal parent and the other from the paternal parent. The make-up of the individual in terms of these genes is known as his "genotype."

Rh₀ phenotypes: The two phenotypes, Rh positive and Rh negative, can be distinguished by using anti-Rh₀ serum.

Rh₀ genotypes: The three genotypes *RhRh*, *Rhrh*, and *rhrh* are based on Landsteiner and Wiener's theory that the **Rh₀** factor is inherited as a simple Mendelian dominant by means of a pair of allelic genes, *Rh* and *rh*. Thus, Rh-negative individuals are always homozygous (*rhrh*). When two Rh-negative individuals marry, they produce only Rh-negative children. Rh-positive individuals may be either homozygous (*RhRh*) or heterozygous (*Rhrh*).

Homozygous: Genetically pure, with genotype consisting of two identical genes. If an Rh-negative expectant mother has a homozygous Rh-positive husband, all the children will be Rh positive.

Heterozygous: Genetically impure, with genotype consisting of two different genes. If an Rh-negative expectant mother has a heterozygous Rh-positive husband, there is 50% chance that the children will be Rh positive and 50% chance that they will be Rh negative, or, as usually stated, 50% of the children will be Rh positive and 50% will be Rh negative.

Rh genes: The series of allelic genes which determine the various sorts of Rh agglutinogens and Rh blood types (see Table 107). Eight distinct varieties have been completely identified, namely, *r*, *r'*, *r''*, *r^s*, *R⁰*, *R¹*, *R²*, and *R^z*. These genes each determine corresponding agglutinogens designated as *rh*, *rh'*, *rh''*, *rh_s*, *Rh₀*, *Rh₁*, *Rh₂*, and *Rh_z*. Note that in order to avoid ambiguity between symbols for genes and agglutinogens, italics are used and the letter "h" is dropped when designating genes. Also, while superscripts and subscripts are both used in the symbols for agglutinogens, only superscripts are used in the symbols for the genes in order to conform with the accepted practice of geneticists. Also note that, in addition to the shorthand symbols *Rh₁* and *Rh₂* (short for *Rh'₀* and *Rh''₀*, respectively), the symbol *rh_s* is used as an abbreviation for *rh'''*, while *Rh_z* is short for *Rh'₀''*. The most common of the eight Rh genes among Caucasoids are *r*, *R¹*, and *R²*, while *R⁰*, *r'*, and *r''* are relatively rare, and *r^s* and *R^z* are extremely rare, so that the last two can usually be disregarded. On the other hand, *R⁰* is the most common gene in Negroids, while *R^z* has its maximum frequency of about 3 to 5% among Mongoloids. When discussing only the results of tests with Rh₀ serum, which divides people into two types, Rh positive and Rh negative, only one pair of genes need be considered, namely, *Rh* and *rh*. Obviously, gene *Rh* comprises four genes, *R⁰*, *R¹*, *R²*, and *R^z*, while gene *rh* comprises four genes, *r*, *r'*, *r''*, and *r^s*.

Allelic genes; allelomorphic genes: Alternative genes situated at corresponding loci in a pair of chromosomes. Thus genes which influence specific characters such as the blood group, eye color, etc., are located at a specific locus on a pair of chromosomes. All the alternate genes which can be located at a given locus are known as allelic. Since the locus for the allelic genes of the A-B-O groups is on a different pair of chromosomes from the allelic genes of the M-N-S types, while the allelic genes of the Rh-Hr system are on a third pair of chromosomes, these three blood group systems are inherited independently of each other. (The Rh locus is not on the sex chromosomes.) When nonallelic genes for two distinct characteristics are on the same pairs of chromosomes, they are said to be **linked**; if they are on different chromosomes, they are said to be **independent**.

Subtyping for rh^w factor: By using anti-rh^w serum, a subdivision of the eight Rh types can be made. Factor rh^w occurs in approximately 5% of Caucasoids, and always in association with factor rh'. Thus type Rh₁ (Rh'₀) is subdivided into Rh₁^w and Rh₁, proper, type Rh₁Rh₂ into Rh₁^wRh₂ and Rh₁Rh₂, proper, and one or two examples of

rare type rh'^w have been found. A similar subdivision of type $rh'rh''$ is theoretically possible. The practical importance of the rh^w factor is to explain rare puzzling examples of erythroblastosis fetalis when both mother and baby are type Rh_1 , where the baby is subtype Rh_1^w and the mother has been sensitized to the rh^w factor.

Anti-Hr sera: Antisera specific for the Hr factors. These are much rarer than anti-Rh sera, since the Hr factors are usually less antigenic than the Rh factors. Three anti-Hr sera are available: anti- hr' , anti- hr'' , and anti- hr . The principal practical value of anti- hr' serum is to subdivide type Rh_1 into the two types Rh_1Rh_1 and Rh_1rh , and the main value of anti- hr'' serum is to subdivide type Rh_2 into Rh_2Rh_2 and Rh_2rh . This gives a presumptive diagnosis of homozygosity or heterozygosity, and aids in anticipating the possible occurrence of erythroblastosis in the unborn child. Anti- hr'' sera are much rarer than anti- hr' . Anti- Hr_0 serum has not yet been found, though a different serum anti- hr has been found.

Rh-Hr types, Rh-Hr phenotypes: Types of human blood demonstrable by the combined use of Rh and Hr antisera. The number of phenotypes which can be distinguished depends on the number of antisera used in the tests, and the evolution of our knowledge as more of the antisera became available is summarized in Table 111. When all three Hr sera as well as the three Rh sera are used, 27 Rh-Hr types can be distinguished corresponding to the 36 theoretically possible genotypes. Since Hr_0 serum has still not been discovered, the examination will usually be confined to tests for hr' , and occasionally for hr'' , in which only 18 phenotypes can be distinguished. It should be emphasized again that many of the phenotypes are quite rare, especially those involving the agglutinogens rh_1 and Rh_2 . In order that the symbols may indicate what tests have actually been made, the "h" is retained when tests have been made for hr' and hr'' only, while the "h" is dropped when tests with Hr_0 have also been made. In selecting the notations for the Rh-Hr type, the principle is employed that the first symbol shall represent the reactions with the Rh antisera, while the second symbol represents the reactions with the reciprocally related Hr antisera. For example, the phenotype Rh_2rh would represent blood reacting with Rh antisera, anti- Rh_0 and anti- rh'' but not with anti- rh' ($Rh_2 = Rh_0 + rh''$), and with Hr antisera anti- hr' and anti- hr'' .

The phenotype corresponding to any given genotype is determined by adding together the effects of the two genes which make up the genotype. For example, if it is desired to know the reactions given by the blood of an individual of genotype R^2r' , one proceeds as follows:

		REACTIONS WITH Rh SERUM			REACTION WITH Hr SERUM		
		Anti- Rh_0	Anti- rh'	Anti- rh''	Anti- Hr_0 (hypothetical)	Anti- hr'	Anti- hr''
Gene R^2	=	+	-	+	-	+	-
Gene r'	=	-	+	-	+	-	+
Therefore by addition genotype R^2r'	=	+	+	+	+	+	+

The phenotype name for blood giving positive reactions with all three Rh sera and all three Hr sera is R_2rh , but since anti- Hr_0 serum to date exists only hypothetically, the name Rh_2Rh_0 is used. If tests are made only with the three Rh antisera, the name Rh_2 must be used.

Rh variants: Some blood specimens give weak or intermediate reactions with one or more of the Rh-Hr antisera, demonstrating the existence of variants of the Rh-Hr factors. Of these, the most important are the variants of the Rh_0 factor, designated \mathfrak{Rh}_0 . \mathfrak{Rh}_0 factor may occur in the absence of factors rh' and rh'' (type \mathfrak{Rh}_0), or in association with rh' but not rh'' (type \mathfrak{Rh}_1), or in association with factor rh'' but not rh' (type \mathfrak{Rh}_2). Rh_0 variants are rare, and occur far more frequently among Negroids than among Caucasoids. In Caucasoids, as many as half of the specimens formerly typed as rh' are now known to belong to type \mathfrak{Rh}_1 . The three agglutinogens \mathfrak{Rh}_0 , \mathfrak{Rh}_1 , and \mathfrak{Rh}_2 are inherited by corresponding allelic genes \mathfrak{R}^0 , \mathfrak{R}^1 and \mathfrak{R}^2 .

TABLE 106.—PROPERTIES OF UNIVALENT AND BIVALENT ANTIBODIES¹

CHARACTERISTIC	BIVALENT ANTIBODIES	UNIVALENT ANTIBODIES
Common name	Agglutinin, precipitin, agglutinating antibody, complete antibody	Glutinin, blocking antibody, conglutinating antibody, incomplete antibody
Usual time of appearance in course of immunization	Early	Late
Resistance to heating	Relatively thermolabile	Relatively thermostable
Reactions of Rh₀ antibodies* in saline medium	Clumps cells by agglutination	Coats cells without clumping them—blocking reaction
Reactions of Rh₀ antibodies in colloid medium	Clumps cells by agglutination	Clumps cells by conglutination
Reaction in presence of complement	Does not fix complement or lyse cells	Fixes complement and lyses cells if the number of antigenic loci on cells surface is adequate; viz., lysis occurs in A-B-O tests but not in Rh-Hr, Kell, or Duffy tests
Behavior in mixed agglutination tests	Specific clumps are formed	Clumps contain more than one kind of cell
Opsonic effect	None	Positive in presence of complement
Chemical nature	Euglobulin; precipitated by sodium sulphate solutions of concentrations 13.5 to 17.4%	Pseudoglobulin; precipitated by sodium sulphate solutions of concentrations 17.4 to 21.5%
Electrophoretic behavior	Alpha and beta globulins	Gamma globulins
Sedimentation constant	17	7
Probable molecular weight	930,000	155,000
Diffusibility	Poor	Good
Behavior relative to placenta	Held back by intact placenta	Passes through placenta readily
Half-life	Probably 2 weeks or less	30 to 35 days
Role in syphilis	Flocculating antibody	Complement fixing antibody
Role in disease	Precipitating and agglutinating antibody	Protective antibody; antitoxin
Role in allergy	Sensitizing antibody (reagin)	Blocking antibody
Role in erythroblastosis	Not significant	Major

*The in vitro reactions are somewhat different, depending on the antigen-antibody system.

¹From Wiener, A. S.: An Rh-Hr Syllabus, The Types and Their Applications, New York, 1954, Grune & Stratton. By permission of the author and the publisher.

Rh-Hr and C-D-E: Use of the letters C, D, E for the Rh-Hr types is bound to lead to confusion and errors, since these symbols are based on a disproved genetic theory (Wiener)¹ and the misconception that blood factors and agglutinogens are identical. C = rh', D = Rh₀, and E = rh''. Thus type rh is cde, type rh' is Cde, type rh'' is

*Omitting genes r^v and R^z.

cdE, type rh_v is CdE, type Rh₀ is cDe, type Rh₁ is CDe, type Rh₂ is cDE, and type Rh_z is CDE. Much confusion exists in the designation of the genotypes with this nomenclature, and it is suggested that it be dropped from the literature.

The Rh antigen was believed at first to be inherited on the basis of a single gene *Rh* and its allele *rh*. As already indicated, Wiener¹ postulated

¹Wiener, A. S.: Science, p. 595, 1944.

that there were actually six allelic genes which might possibly occupy a single locus in the chromosome. In 1941 Levine² described on the basis of the antibody in the serum of the blood what was essentially just the opposite to Rh and he called it Hr. The necessity of including this antigen within the sphere of the Rh antigen led to the possibility of another theory by Fisher and Race.³ However, this theory had previously been disproved and discarded by Wiener.

In an editorial^{3a} J. M. Hill discussed this entire question. He advised that in the light of present knowledge it seems best to abandon all concepts of dominance of Rh genes whether relative or absolute and simply consider all Rh types as determined by allelomorphic genes without dominance.

*Tests which need not be made because the reactions in these combinations are invariably positive, except for types rh'rh'' and Rh₁Rh₂ in the case of individuals carrying the rare genes *r''* and *R²*. Should these tests be done and negative reactions obtained, there has been an error in technic, and the entire examination should be repeated.

†These are phenotypes and the symbols have been selected so as to indicate what tests have actually been done and what reactions were obtained. For example, type Rh₁ indicates that tests have been made only with sera anti-rh', anti-rh'', and anti-Rh₀, and positive reactions obtained with anti-rh' and anti-Rh₀ and a negative reaction with anti-rh''; on the other hand, type Rh₁Rh₁ indicates type Rh₁ blood which also has been tested with anti-hr' serum with which it gives a negative reaction.

Professor R. A. Fisher's synthesis of the results of the British work on the isolation of Rh genes was briefly described by Race (1944). The Fisher-Race theory proposes that there are three possibly unlike genes which determine the Hr and Rh phenotypes of an individual. These genes are designated *C-c*, *D-d*, *E-e*, and the appropriate combinations of these result in the definite type of individual.

Coombs, Mourant, and Race⁴ have discussed Fisher's views very completely in an article entitled, "A New Test for the Detection of Weak and Incomplete Rh Agglutinins." They stated that Fisher, noticing the mutually antithetical reactions of two of the four distinct types of sera then known (Race, Taylor, Cappell, and McFarlane, 1944) supposed that these two sera were reacting with allelic antigens. One of the antigen Fisher called *C*, and its allele *c*. The two remaining sera did not give antithetical reactions, so the antigens which they recognized were not allelic to each other though they presumably each had an

* This table does not include hypothetical genes R^{2w} and R^{2y} , which, if they exist at all, are very rare.
† In this table Rh₁ is used as a short designation for Rh₀; Rh₂ is short for Rh₀; rh_y is short for rh''; and Rh₂ is short for Rh₀.

† The reduction in the frequency of type rh' as compared with that given in earlier charts can be attributed to recognition of bloods of type Rh₁ (containing Rh₀ variant) which are now included in type Rh₁ instead of rh'. The agglutinogens Rh₀, Rh₁, and Rh₂, and their corresponding genes R⁰, R¹, and R², are not

given here, because this would serve unnecessarily to complicate the chart, by increasing the number of possible genotypes to 91. Also, no attempt is made to include certain rare exceptional bloods, such as those lacking both factors rh' and hr', and/or lacking both rh'' and hr'', etc.

§ Based on the estimated gene frequencies, $r = 0.38$, $r' = 0.06$, $r'' = 0.05$, $r^w = 0.001$, $r^y = 0.0006$, $R^0 = 0.27$, $R^1 = 0.41$, $R^2 = 0.15$, $R^2 = 0.02$, and $R^w = 0.2$.

From Wiener, A. S.: Vox Sanguinis, May, 1954.

allele. Instead of seven alleles of the Rh gene at one locus as had previously been proposed, Fisher pictured three adjacent loci each with two alleles, each allele corresponding to an antigen which was capable of reacting with one antibody only, as shown diagrammatically as follows:

Antibodies	Loci on Chromosome	Antibodies
Γ	C or c	γ
Δ	D or d	δ
H	E or e	η

The hypothesis required two more antibodies, δ and η , unknown at that time. Mourant (1945) has found η . Thus Fisher predicted the existence of three antisera reciprocally related to the three principal anti-Rh sera. At the time this prediction was made, one of these antisera, anti-**hr'** (or anti-c) was already known. Of the remaining two, only one, anti-**hr''** (or anti-e) has been shown, with certainty, to exist. Instead of anti-**Hr₀** (anti-d), recently a different antiserum, anti-**hr** (or anti-f) has been found, which was not predicted by Fisher.

TABLE 112.—Rh ANTIBODIES AND AGGLUTINOGENS

Original names Fisher's antigenic or genetic notation Antibodies			Agglutinogenst

anti- hr	None*	None*	—	—	+	+	—	—	—	—

*No name given by Fisher or Cappell; anti-f used by Rosenfield et al.
†One must not confuse the agglutinogens with the types. The types (phenotypes) being determined by a pair of genes (genotypes) therefore necessarily comprise a pair of agglutinogens.

It may be convenient at this point to summarize the contributions made by British investigators to the field of blood grouping during the past decade. This was initiated in 1942 by Taylor and Race, following publication of the American investigations on the Rh factor. After Taylor's premature death, Race took over the leadership of British work, and soon confirmed and extended American reports on the serology and heredity of the Rh-Hr blood types. By studying difficult problems of multiple sensitization, he and his collaborators discovered the blood factors **rh^w**, *Levay*, and *Lutheran*. These and other contributions of British investigators are well summarized in the book of Race and Sanger, the second edition of which has just appeared.⁵ Mourant, codiscoverer of the *Lewis* factor, has published an important book⁶ summarizing recent advances in anthropologic aspects of the subject. Molli-son, who with Cutbush and Parker discovered the Duffy (**F**) factor, studied exchange transfusion and published a fine book on blood transfusion,⁷ while

Pickles contributed a book on erythroblastosis fetalis.⁸ Finally, Dacie has specialized in the study of autosensitization and has recently published a book on hemolytic anemia.⁹

I. Tests for the Determination of the Rh Factor

(1) Detection of the Rh Factor in Blood Cells

A requisite for accurate and successful Rh testing is an efficient anti-Rh serum. It is unfortunate that while the best source of anti-Rh serum is from women who have given birth to erythroblastotic babies or who have had spontaneous abortions or stillbirths resulting from Rh incompatibility, many of these sera do not contain sufficient anti-Rh agglutinins to be used in routine tests. Potent anti-Rh sera are produced by immunizing normal male professional blood donors (see page 1072).

Disadvantages of sera derived from animals immunized to rhesus monkey blood are (1) if guinea pigs are used, the amount of blood obtainable is small; (2) it is commonly believed that absorption with Rh-negative blood cells is necessary to remove undesirable antibodies of such sera; and (3) these animal sera affect only one of the several kinds of Rh factor, but this happens to be the most common type. To identify all the Rh-positive bloods, tests made with animal sera must be supplemented by tests with other sera.

(A) Slide Method.—Anti-Rh₀, anti-Rh₀', and anti-Rh₀'' agglutinating sera for the slide test for Rh testing of human blood cells are now available commercially.* These sera are produced by immunizing normal male professional blood donors. Anti-Rh₀ serum shows 85 per cent of all bloods tested to be Rh₀-positive. If only anti-Rh₀' serum is used, slightly less than 87 per cent of all bloods tested will be positive. If only the anti-Rh₀'' serum is used, about 85.5 per cent of all bloods will be positive.

When testing recipients, use the anti-Rh₀ serum routinely, and if the individual is Rh negative by this test, give only Rh-negative donor blood in a transfusion. If the blood is Rh positive, give Rh-positive blood.

When testing donors, if all three antisera are used, if the blood is negative using the anti-Rh₀ serum, but positive by either or both of the other two, give this blood only to Rh-positive recipients. If positive by all three tests, of course give this blood only to Rh-positive recipients. If negative by all three antisera (type rh), give to Rh-negative recipients.

Reagents.—

For recipients, use anti-Rh₀ slide (agglutinating) serum; use anti-Rh₀, anti-Rh₀' and anti-Rh₀'' slide serum for donors. (If blood bank blood is used, the exact type of blood of the donor is probably given on the blood bottle. This can be detected by use of the tube-agglutinating method. See below.)

Equipment.—

A special viewing box is used for this test. This box is fitted with an electric light globe which will bring the temperature on the plate to 45° to 47° C. See Fig. 232. Since some time is required to bring the temperature on the glass plate to the proper temperature, the light should be on at all times.

Ordinary glass microscopic slides are used.

*Antisera are available from the Certified Blood Donor Service, Jamaica, N. Y., High Titer Serum Laboratory, New York City, Hyland Laboratories, Los Angeles, Calif., and Yonkers, N. Y., American Hospital Supply Corporation, Chicago, and others.

⁸Pickles, M. M.: *Haemolytic Disease of the Newborn*, Oxford, 1949, Blackwell Scientific Publications, Ltd.

⁹Dacie, J. V.: *The Haemolytic Anemias*, London, 1954, J. & A. Churchill, Ltd.

In addition to the antisera, **whole blood** taken in a special anticoagulant is used. (See page 1005.) If clotted blood is submitted, break up the clot and suspend the cells to a concentration of 50% in their own serum. Do not use blood taken in a crystalline solution (saline, sodium citrate, liquid oxalate, etc.). Blood taken from patients with anemia must be centrifuged and enough plasma removed to bring the cell concentration to 50%.

Technic.—

- Carry out the method for each antiserum used.
- Make a large oval ring, using a red wax pencil, on a glass slide, about 1½ in. by ¾ in. Label with the name of the individual being tested and the serum used. See Fig. 240.
- Place 2 drops of whole blood on the slide.
- Add 1 large drop of antiserum (anti-Rh₀ if this is the recipient).
- Prepare similar slides for each antiserum used to test the blood.
- Mix with a wooden applicator and spread the mixture over the entire surface of the oval ring.
- Place on a preheated viewing box and rock back and forth, observing for clumping or lack of clumping.
- At the end of 3 to 5 minutes, tip the box up and add a drop of saline to the top of the slide so that it runs down into the mixture. Rouleaux will be broken up by the saline, but true clumping will not.
- Read macroscopically only; do not read under a microscope.
- Wait for a minute or two before taking the final reading.
- Report clumping as positive, lack of clumping as negative.

Controls:

At the same time, run duplicate tests using known Rh-positive and Rh-negative whole blood as controls. If these react correctly, the results in the tests may be reported. If the controls give incorrect reactions, do not report the results of the tests until new sera are obtained and the tests have been repeated.

Results Possible:

For the **recipient**, see Table 113; for the **donor**, Table 114.

TABLE 113.—THE RECIPIENT

WHOLE BLOOD PLUS ANTI-Rh ₀ SERUM	CONCLUSIONS
+	Rh ₀ positive: give Rh-positive blood
-	Rh ₀ negative: give Rh-negative blood

-	+	+	Type rh _y * (rh'rh'') {
+	-	-	Error
+	-	+	Error
+	+	-	Error

*Give this blood only to Rh-positive patients. This individual should receive only Rh-negative blood unless the exact type is available. Tests for Rh₀ factor may be made.

(B) Tube Method.—

This test should be made routinely on all Rh-negative patients and on Rh-negative donors.

Reagents.—

Anti-rh' saline agglutinating serum, anti-rh'' saline agglutinating serum, anti-Rh₀ saline agglutinating serum, anti-Rh₀ conglutinating (slide test) serum.

In addition to these sera, a 2 or 3% suspension of the patient's (or donor's) cells in saline is needed. Make the suspension as directed on pages 1005 and 1006, wash once in saline, and resuspend to a 2 or 3% suspension in saline.

Use tubes 7.5 cm. by 8 mm., 4 for each test.

TUBE TEST FOR Rh FACTORS

○ Anti-Rh ₀ slide serum	○ Anti-Rh ₀ slide serum
○ Anti-Rh ₀ tube serum	○ Anti-Rh ₀ tube serum
○ Anti-rh'' tube serum	○ Anti-rh'' tube serum
○ Anti-rh' tube serum	○ Anti-rh' tube serum
Patient's cells	Donor's cells

Water bath 1 hour at 37°C.
If negative with anti-Rh₀ tube serum, do Coombs test in tube with anti-Rh₀ slide serum.

Fig. 249.

Fig. 250.—Tube test for Rh factors in cell suspensions.

Technic.—

Label tubes with the identification of the individual being tested and the name of the serum.

Place 1 drop of the cell suspension to be tested in each of four tubes, in a rack. Use the same dropper held at the same angle so that the drop used in each tube will be approximately the same size.

- Add a drop of anti-rh' saline agglutinating serum to tube 1
- a drop of anti-rh'' saline agglutinating serum to tube 2
- a drop of anti-Rh₀ saline agglutinating serum to tube 3
- a drop of anti-Rh₀ slide agglutinating serum to tube 4

Mix and incubate in a water bath at 37° C. for 1 hour.

Tip the rack and take a preliminary reading from the bottoms of the tubes (see Fig. 251). Negative reactions come down in a pear shape, while positives tend to remain round.

Read over a lighted box, spreading the mixture thin in the tube.

Read under a scanning lens of a microscope, reporting clumping as positive and lack of clumping as negative.

If the result in tube 3 is negative, use *tube 4* for a Coombs test.

Wash the cells in tube 4 three times with saline. After the last washing, remove all traces of the saline. This can be accomplished by centrifuging at high speed, turning the tube upside down after the cells have been packed, and tapping the lip of the tube on a gauze pad while the tube is still upside down.

TABLE 115.—RESULTS POSSIBLE WITH THE TUBE TEST FOR Rh FACTORS

CELLS + ANTI-rh' SERUM	CELLS + ANTI-rh'' SERUM	CELLS + ANTI-Rh ₀ SERUM	CELLS + ANTI-Rh ₀ SLIDE SERUM (PLUS COOMBS TEST)	CONCLUSIONS (Rh TYPE)
-	-	-	$\frac{-}{-}$	rh
+	-	-	$\frac{-}{-}$	rh'
-	+	-	$\frac{-}{-}$	rh''
+	+	-	$\frac{-}{-}$	rh _y
-	-	+		Rh ₀
+	-	+		Rh ₁
-	+	+		Rh ₂
+	+	+		Rh _s
-	-	-	$\frac{+}{-}$	Rh ₀
+	-	-	$\frac{+}{-}$	Rh ₁
-	+	-	$\frac{+}{-}$	Rh ₂
+	+	-	$\frac{+}{-}$	Rh _s

Shake thoroughly, and incubate for 5 minutes in a water bath at 37° C.

Add a drop of Coombs serum.

Mix thoroughly, and centrifuge at 500 to 1,000 r.p.m. for 2 minutes.

Read over a lighted box and under a scanning lens.

If the results in tube 3 (anti-Rh₀ saline agglutinating serum) are positive, do not do the Coombs test on tube 4, because it will always be positive under these circumstances.

If the anti-rh' serum clumps the cells, rh' factor is present.

If the anti-rh'' serum clumps the cells, rh'' factor is present.

If the anti-Rh₀ saline agglutinating serum clumps the cells, Rh₀ factor is present.

If the anti-Rh₀ saline agglutinating serum fails to clump the cells, but the Coombs test is positive in tube 4 (slide agglutinating anti-Rh₀ serum), the Rh₀ variant is present. This is reported thus:

- | This means that the original test was negative and also the Coombs test
- . (in the box).
- + | This means that the original test was negative and the Coombs test was
- positive (in the box).*

Sensitivity tests may be run on the serum to detect isoimmunization to the Rh factor at the same time as the tests for the Rh factor are made. If desired, also make the tests for the Hr factors. The tests for Hr will always be positive on Rh-negative persons; therefore, it is best to wait for the results of the Rh tests before using serum to make tests for the Hr factors.

Fig. 251.—Magnification 1:2. 1 and 2, Negative reactions; the inner light disk in 2 is due to slight convexity in the bottom of the tube. 3, Faintly positive reaction. 4, Weak reaction. 5 and 6, Typical positive reactions. (From Landsteiner and Wiener: J. Exper. Med. 74: 312, 1941.)

(2) Test for the Hr Factor in Blood Cells

(A) Open Slide Method.—

Prepare oxalated whole blood as directed on page 1056.

Obtain slide serum (conglutinating serum), anti-hr' and anti-hr''.

Prepare two slides by marking them with a large oval using a red wax pencil. Label properly.

Place 2 drops of oxalated whole blood on a slide.

Add 1 drop of the antiserum, anti-hr' on one slide, anti-hr'' on the other.

Mix each with a separate applicator and spread the area of the oval.

Place on a lighted viewing box, and rock back and forth for 3 to 5 minutes.

Add a drop of saline and let it run down the specimen. If rouleaux are present, they will break up. Read after 2 more minutes.

Report clumping as positive and lack of clumping as negative.

Results Possible: See Table 116.

TABLE 116

ANTI-hr' SERUM PLUS WHOLE BLOOD	ANTI-hr'' SERUM PLUS WHOLE BLOOD	CONCLUSIONS.
-	-	hr' and hr'' negative
+	-	hr' positive
-	+	hr'' positive
+	+	hr'hr'' positive

*After Lester J. Unger, New York City.

(B) Tube Test.—

Only the test using anti-hr' saline agglutinating serum will be given. Prepare one tube for each antiserum.

Place 1 drop of the unknown washed cells suspended to 2 or 3% suspension in saline in the tube.

Add 1 drop of anti-hr' saline agglutinating serum.

Mix and incubate in a water bath at 37° C. for 1 hour.

Take "bottom readings," and then read over a lighted box and under a scanning lens of a microscope.

Report clumping as positive and lack of clumping as negative.

Clumping means that the blood is hr'-positive, and lack of clumping means it is hr'-negative.

It is not necessary to make Hr tests on Rh-negative blood since it will always be hr' and hr'' positive.

Consult Table 111, page 1053, for results if both Rh and Hr tests are made on a specimen of blood.

II. Detection of the Anti-Rh Agglutinin in Blood Serum

There are two distinct types of antibody formed in blood serum as a result of isoimmunization with the Rh agglutinin: (1) an Rh agglutinin; (2) an antibody which when mixed with saline-suspended Rh-positive cells does not agglutinate them. In fact, its presence prevents agglutination of these cells even when they are all exposed to a good anti-Rh serum. This refers to the so-called "blocking" antibody. Rh-positive blood cells, however, will be clumped with the slide and tube tests (pages 1055 and 1056).¹ Wiener found that by the use of normal plasma instead of saline solution as a diluent for the blood cells, such an antibody will clump Rh-positive cells in the test tube. Bovine serum albumin also activates "blocking" antibodies. Serum albumin also has the power to cause the blocking antibody to bring about clumping.² The mechanism by which serum albumin fractions exert their effects is not clear.

**THE BLOCKING ANTIBODY AND THE ZONE PHENOMENON IN HUMAN
ANTI Rh SERUM** (see page 1038)

Wiener and Peters³ showed that sensitization of Rh-negative individuals against the Rh factor can often be detected by in vitro tests for anti-Rh agglutinins in the serum. It was found, however,^{4, 5} that there were many Rh-negative patients, strongly sensitized to the Rh factor, whose plasma did not contain demonstrable anti-Rh agglutinins. These patients had either intragroup hemolytic transfusion reactions or had delivered babies with erythroblastosis fetalis.

In searching for an explanation of the lack of in vitro agglutination by these sera, Wiener mixed the sera with group O Rh-positive cells, and later added known anti-Rh serum to the same test cells. The cells were not agglutinated by the known anti-Rh serum after they had been in contact with the patients' sera. He concluded that the action of the active agglutinin in

¹Diamond, L. K., and Abelson, N. M.: *J. Lab. & Clin. Med.*, **24**: 122, 1945.

³Wiener, A. S., and Peters, H. R.: *Ann. Int. Med.* **13**: 2306, 1940.

⁴Wiener, A. S.: *Arch. Path.* **32**: 227, 1941.

⁵Levine, P., Burnham, L., Katzin, E. M., and Vogel, P.: *Am. J. Obst. & Gynec.* **42**: 925, 1941.

the added serum had been blocked, and designated such antibodies as were present in these patients' sera as "blocking antibodies." Fig. 252 is a diagrammatic representation of the difference between Rh agglutination and blocking reactions.

Tests were carried out on a number of patients with erythroblastotic infants where the usual tests for anti-Rh agglutinins were unsuccessful, and in most of the cases clear-cut blocking reactions were obtained, thus demonstrating the presence of a special type of Rh antibody. The reaction is specific in that it is obtained only with sera from Rh-negative individuals sensitized by the Rh factor, and not with sera from Rh-positive or Rh-negative individuals not sensitized by the Rh factor.

Fig. 252.—Diagrammatic representation of Rh agglutination and blocking reactions. (Wiener, A. S.: *Am. J. Clin. Path.* 15: March, 1945, by permission of the author and publisher, Williams & Wilkins Co.)

A number of human anti-Rh sera have been obtained which exhibit a marked "prozone" effect.^{6, 7} Taylor and associates⁶ attempted to explain the behavior of such sera on the basis of optimal proportions of antigen and antibody. This does not explain why the phenomenon does not occur more frequently. Wiener's experiments suggest that such prozone phenomena are due to the presence in sera of a mixture of blocking and agglutinating antibodies, the agglutinating antibodies being of a higher titer.

Those sera which exhibit the prozone effect cannot be used as diagnostic reagents unless the agglutinin is far more active than the blocking antibody. Experiments seem to indicate that some of these sera can be absorbed with Rh-positive blood, so that after the blocking antibody is specifically removed, the treated serum becomes a useful diagnostic reagent. From a practical standpoint, the significance of these findings lies in the fact that the characteristics of the agglutinating antibody and the blocking antibody are sufficiently clear cut, so that, for example, there is no difficulty in the use of an anti-Rh serum which contains an anti-**rh'** agglutinin and also an anti-**Rh₀** blocking antibody.

⁶Taylor, G. L., Race, A. M., and Ikin, E. W.: *Brit. M. J.* 2: 572, 1942.

⁷Levine, P.: *Arch. Path.* 37: 83, 1944.

It is often necessary to determine the presence in the patient's blood serum of anti-Rh antibodies. Three tests are commonly made: (1) the agglutination test; (2) the blocking test; and (3) the conglutination test. These tests are made simultaneously, and are referred to as "sensitivity" tests.

(1) Sensitivity Test for Rh-Hr Antibodies in Serum Method of Unger

Sensitivity tests for Rh-Hr antibodies should be made of the sera of both the patient and the donors. These tests should be made routinely even when the cross-matching tests are compatible. If present, they might be responsible for post-transfusion reactions if the cells for which they are specific are transfused. This occurs particularly when the patient has **hr'** or other rarer antibodies and receives blood for which the antibodies are specific.

For further discussion, refer to the section on Rh-Hr, pages 1024 ff.

Technic.—(See Fig. 241.)

Have at hand group O Rh_zRh₀ cells. Group O is used because the unknown serum might contain anti-A or anti-B agglutinins which would react with cells derived from groups A, B, or AB, but not with group O. Type Rh_zRh₀ cells are selected because they react with anti-rh', anti-rh'', anti-Rh₀, anti-hr', and anti-hr'' antibodies.

Prepare three cell suspensions:

- (a) Untreated and saline-suspended, 2 or 3% suspension.
- (b) Trypsinated and saline suspended, 2 or 3% suspension.
- (c) Suspended in their own plasma, 5% suspension. Refer to page 1006 for preparation of these suspensions.

Use three tubes, 7.5 cm. by 8 mm. for each serum tested.

Place 1 drop of untreated saline-suspended group O Rh_zRh₀ cells in the first tube, 1 drop of group O Rh_zRh₀ trypsinated cells in the second tube, and 1 drop of group O Rh_zRh₀ cells suspended in their own plasma in tube three.

Add a drop of the serum to be tested to each tube, and shake.

Incubate in a water bath at 37° C. for ½ hour.

Tilt the tubes back and forth gently over a lighted viewing box and observe for clumping or lack of clumping. Read under a scanning lens of a microscope. If any tube appears to have clumps, the individual is sensitized, and has antibodies against the Rh-Hr factors. If all tubes appear to be negative, proceed with the antiglobulin test.

Antiglobulin tests are made on negative-reacting untreated and trypsinated cells, saline-suspended.

Add saline to each tube, to full capacity.

Centrifuge to pack, and pour off the supernatant saline.

Shake and add more saline, centrifuge, remove saline, and shake again. This is the second washing.

Add more saline, and centrifuge to pack the cells firmly. Pour off the supernatant saline and tap the tube upside down against a gauze pad to remove all traces of saline.

Shake to dislodge the cells.

Incubate 5 minutes at 37° C.

Add a drop of antihuman globulin serum (Coombs test) to each tube.

Mix and centrifuge at 500 to 1,000 r.p.m. for 2 minutes.

Gently dislodge the sediment and tip back and forth and read under a scanning lens of a microscope.

If clumping occurs, the individual is sensitized, and an antibody is in the serum specific for a factor present in the clumped cells. Its specificity remains to be determined. If it occurs with saline-suspended cells without the addition of antiglobulin serum, there are agglutinating, bivalent antibodies in the serum. If it occurs with trypsinated cells or upon the addition of anti-

globulin serum, or with cells suspended in their own plasma, but not with saline-suspended cells, there are blocking, or univalent, antibodies present.

If any clumping occurs, this must be reported. If it occurs with donor's serum, reject the donor. If it occurs with patient's serum, report to the director of the laboratory and prepare for an identification and a titration of antibodies.

If no group O Rh₊Rh₀ cells are available, do the 6-tube test, using group O Rh₊, O Rh₊, and O rh untreated and saline suspended cells, and the same series of types but trypsinated and saline suspended. Run Coombs tests on negative tubes containing untreated and trypsinated saline-suspended cells (**Unger test**).

(2) The Conglutination Test for Sensitivity to Rh-Hr Factors

The conglutination test requires that the cells be suspended in their own plasma, and therefore the sensitivity tests of Unger as described above fulfill this requirement. If the Unger method is followed, no further conglutination test need be made.

In the case of Rh-negative pregnant women who have had previous transfusions or pregnancies, Rh antibody titrations should be made before the third month to determine whether antibody is being carried into their present pregnancies. When antibody is demonstrated, titrations should be made at monthly intervals until the seventh month, and at biweekly intervals thereafter until the last month, when they should be done weekly. When the titrations at the third month do not demonstrate Rh antibody, no further studies need be made until the seventh month.

The appearance of antibody or rising titer when antibody is demonstrated at the third month proves that immunity is stimulated and the fetus is Rh positive. An unchanging or falling titer proves that immunity has not been stimulated; the fetus may be Rh positive or Rh negative.

(3) Indirect Test for Blocking Antibodies (Wiener)

Technic.—

Carry out the test in small Kahn test tubes. Use 1 drop of the patient's serum mixed with 1 drop of a saline suspension of group O Rh₊Rh₀ red cells.

Incubate for 1 hour in a water bath at 37° C.

Centrifuge at 1,000 r.p.m. for 1 minute. Read under a scanning lens. If the reaction is positive, anti-Rh agglutinins are present in the patient's serum.

If the reaction is negative, decant all the saline, after centrifugation.

Add to the same tube 1 drop of known anti-Rh₀ agglutinating serum.

Mix and again place in a water bath at 37° C. for 1 hour. Centrifuge and read.

If agglutination now occurs, then the patient's blood serum contained neither anti-Rh₀ agglutinins nor Rh₀ blocking antibodies.

If no agglutination occurs, the patient's serum contains Rh₀ blocking antibodies, otherwise the known Rh-positive cells would have reacted with the added known anti-Rh₀ serum.

(4) Direct Antiglobulin Test of Cord and Infant's Blood* (Also spoken of as the Coombs Test) (for Rh Blocking Antibodies Derived From the Mother)

The antiglobulin test is used routinely whenever antibodies which react to antihuman globulin addition are to be detected. These are the univalent

*This test for coating of the baby's cells by Rh antibodies was first described by Wiener and Sonn: *Am. J. Dis. Child.* 71: 25, 1946. (cf. Wiener, A.S.: *The Rh-Hr Types*, New York, 1954, Grune & Stratton.)

or blocking antibodies. These antibodies are also detected by the blocking, agglutination, and enzyme techniques.

The direct antiglobulin test is also used to detect the presence of univalent (blocking) antibodies coating the red cells of erythroblastotic infants after birth.* These univalent antibodies, when present, have been derived from the isosensitized mother, and are considered the cause of erythroblastosis fetalis. When they are found, the baby is in danger of developing clinical signs of erythroblastosis fetalis, and an exchange transfusion should be performed, using Rh-negative donor blood. (See pages 1075 ff.)

Technic.—

Wash the baby's blood cells three times with saline. After the last washing, tap the tube upside down over a gauze pad to be sure that all the saline has been removed.

Resuspend the cells to approximately 2% suspension in saline.

Place 2 drops of the washed saline-suspended cells in a tube 7 by 70 mm., scrupulously clean. See Fig. 253.

Fig. 253.

Add 2 drops of antihuman globulin (Coombs) serum.

If the cells have been strongly sensitized by the maternal antibodies, clumping will become visible almost immediately. Examine over a lighted viewing box.

If there is only a weak reaction, or if the reaction appears to be negative, allow the tube to stand at room temperature for 15 to 30 minutes.

Centrifuge at 500 r.p.m. for 2 minutes.

Observe for agglutination over a lighted viewing box and under a scanning lens.

Agglutination means that the infant's cells have been coated with blocking antibodies derived from an isosensitized mother. Lack of agglutination means that the baby's cells are not coated.

Controls.—

Controls are made in small tubes.

- (1) 2 drops of washed infant's cells plus 2 drops of saline.
- (2) 2 drops of Rh-positive cells, saline suspended, plus 2 drops of antiglobulin serum.
- (3) If desired, prepare Rh-positive cells by coating them with known blocking antibodies. Add 2 drops of 2% suspension of Rh-positive saline-suspended cells to 2 drops of known Rh blocking serum. Incubate at 37° C. for 30 minutes. There should be no agglutination. Centrifuge and remove the supernatant saline, and wash three times with saline. Add 2 drops of Coombs serum (antiglobulin). The cells should now clump.

*As Wiener has pointed out, coating of the baby's cells can also be demonstrated by the blocking and direct agglutination tests.

(4) 2 drops of Rh-negative cells, plus 2 drops of antiglobulin serum.

Handle the controls in the same manner as the test.

Tubes (1), (2), and (4) should give negative reactions.

The antihuman globulin serum may give a false negative direct or indirect reaction when the red blood cells are coated with a minimal amount of antibody.

Prepare a 1:5 dilution by adding 1 drop of the antihuman globulin to 4 drops of saline. Use 1 drop in the test.

Antihuman globulin serum (Coombs serum) is prepared by hyperimmunization of a rabbit against human serum globulin. Nonspecific antibodies are absorbed from the serum by adding human red cells which have been washed 10 times with saline solution.

(5) Indirect Antiglobulin Test (Coombs Test) for Detection of Isoimmunization¹

See Rh-Hr Sensitivity Testing, page 1062.

(6) Quantitative Direct Antiglobulin Test (Wiener²)

This is a test for measuring the degree of coating of red cells by antibodies from an erythroblastotic infant or a patient with hemolytic anemia.

Wash the red cells to be tested 4 times with an excess of saline, as for the simple direct antiglobulin test.

Titrate the antiglobulin serum against these washed cells.

At the same time titrate the antiglobulin serum against Rh-positive cells which have been maximally coated by sensitizing them with an anti-Rh agglutinating (slide test) serum having a titer well in excess of 16 units by the albumin-plasma method (p. 1080).

Calculate the percentage of coating of the unknown cells by dividing the titer of the antiglobulin serum for these cells by its titer for maximally coated Rh-positive cells, and then multiplying by 100.

This method can be applied to determine the relative number of antigenic points in the discoplasm for agglutinogens of different blood group systems. It is also applied in babies with erythroblastosis as an additional criterion of severity, and in patients having acquired hemolytic anemia, where it has been found that the degree of coating is correlated with the clinical manifestations. Thus a rise in the degree of coating may be associated with a hemolytic crisis, while a decrease may presage a remission. Disseminated lupus erythematosus appears to be one of the milder manifestations of auto-sensitization, and this view is supported by the results of the quantitative direct antiglobulin test.

III. Titration of Rh Antibodies in Serum and Identification of Specificity

Rh antibody titrations are made on all Rh-negative sensitized patients, and on all other bloods as ordered. The serum of Rh-positive patients sensitized against specific Rh factors is also titrated against these specific cells. For example, serum from Rh-negative patients is titrated against the following cells: (1) group O type Rh₁Rh₁ (if not available, use type Rh₁rh); (2) group O type Rh₂rh; (3) group O type rh'rh; (4) group O type rh''rh; and (5) group O type rh (triple Rh negative).

¹Coombs, R. R. A., Mourant, A. E., and Race, R. R.: *Brit. J. Exper. Path.* 26: 255, 1945.

²Wiener, A. S., and Gordon, E. B.: *Am. J. Clin. Path.* 23: 5, 1953.

If the patient lacks **Rh₀** but has **rh'**, the blood is not titrated against the **rh'**. If the patient is sensitized against the **Hr** factors, the serum is titrated against Rh-negative blood, and Hr-negative blood is used as a control instead of Rh-negative (Rh-negative blood is Hr-positive).

Six titrations are run simultaneously:

- (1) Saline agglutination titer for bivalent antibodies.
- (2) Trypsinated cell titer.
- (3) Indirect blocking antibody titer, for univalent antibodies.
- (4) Antihuman globulin titer, for univalent antibodies.
- (5) Albumin-plasma titer, for univalent antibodies.
- (6) Trypsinated cell-antihuman globulin titer, for univalent antibodies.

The serial dilutions which are used are: 1:1, 1:2, 1:4, 1:8, 1:16, 1:32, 1:64, 1:128, 1:256, and 1:512. Additional dilutions are made if the titer is 1:512 or higher.

If the sensitivity tests which were made before the titration indicate that the antibody titer will be weak, some of the tubes may be omitted.

Three racks of 10 holes and 4 rows are needed for the titration proper (two for saline-suspended cells, and one for trypsinated cells), and one rack is used to make the serum dilutions. A rack with 2 rows of holes may be used to make the dilutions. The technic of handling dilutions is extremely important; no traces of serum or of the various dilutions must be carried from one tube to another, as that would erroneously increase the titer.

The cells needed are listed above. One set must be untreated and suspended in saline to a 2 or 3 per cent suspension; they are washed once before being suspended. Trypsinated cells are prepared as usual (see page 1006), and resuspended to a 2 or 3 per cent in saline.

Albumin-Plasma Mixture.—

Pool a number of groups O, A, and B plasmas.

Centrifuge and remove the clear plasma.

Measure 8 drops of 30% bovine albumin into a tube.

Rinse the dropper with the pooled plasma, discarding each dropperful of rinsing plasma.

Do this 2 or 3 times depending on how much plasma there is. This is to remove the bovine albumin from the dropper without admitting any water or saline.

Using the same dropper, add 32 drops of the pooled plasma, so that there is 1 part of the albumin to each 4 parts of pooled plasma.

Mix the albumin-plasma mixture in and out of the dropper before using.

For the indirect blocking test, anti-**Rh₀** saline agglutinating serum will be needed.

When the titrations have been prepared, the first row of tubes in the titration racks will contain serially diluted serum plus group O **Rh₁Rh₁** cells; the second row, the serially diluted serum plus group O **Rh₂rh** cells; the third row, group O **rh'rh** cells (5 tubes unless a high titer is anticipated); and the fourth row, the first two tubes will contain serially diluted serum and group O Rh-negative cells, and serially diluted serum plus group O **rh''rh** cells in the second half of the fourth row.

In rack 2, controls are run on the various cells suspended in saline, plus the albumin-plasma mixture, to be sure that these cells do not agglutinate in the albumin-plasma mixture without the patient's serum.

One drop of each serum dilution is used for each drop of cells.

Actual Technic of the Titration (see Fig. 254).—

Dilutions and titrations are made at the same time so that the same dropper can be used throughout the procedure, insuring uniform drops in each tube.

Rack up the three racks of tubes, 7.5 cm. by 8 mm., for the titrations. Be sure to label at least the first tube in each row. Use a different color wax pencil for the trypsinized cells titrations. When antiglobulin tests are carried out, each tube must be labeled.

Rack up a set of Kahn tubes in two rows of 10 tubes each to make the dilutions of serum.

Use serum, NOT plasma, for the titration whenever possible.

Place the serum in tube 1 of the front row of the dilution rack. Leave the other 9 tubes in that row empty. Label the tubes 1:1, 1:2, 1:4, 1:8, 1:16, 1:32, 1:64, 1:128, 1:256, and 1:512, respectively.

Fill all the back row of dilution tubes with saline. There are now two rows of Kahn tubes, the first row empty except for serum in the first tube, and the second row of tubes filled with saline.

Put 1 drop of the undiluted serum into the first tube of each row in the titration.

Using the same dropper, carry 20 drops from the first tube of serum to the second tube in the front row of the dilution rack.

Rinse the dropper with all the saline in tube 1 of the back row of dilution tubes, and remove the discarded saline tube from the rack. Wipe off the excess saline with a gauze pad.

Put 20 drops of clean saline into each tube of the dilution rack, front row, beginning with tube 2, and using the same dropper which has been rinsed with saline.

Mix the contents of tube 2 thoroughly in and out of the dropper, avoiding bubbles.

Transfer a drop of this dilution into each second tube of the titrations, holding the pipette at the same angle throughout, and being careful not to add bubbles, for these are not full drops.

Carry 20 drops of diluted serum from tube 2 to tube 3 of the dilution rack.

Rinse the dropper with the saline in the tube behind tube 2, using all the saline, and wiping off the excess on a gauze pad.

Mix contents of tube 3 thoroughly, in and out of this same dropper, carry a drop to each tube 3 in the titrations, and carry 20 drops to tube 4 in the dilution rack.

Rinse the dropper with the saline behind tube 3, and continue in the same manner as above, until all dilutions have been made, and all the tubes in the titration racks have received their respective diluted serum, one drop each.

Do not put any of the diluted serum in the control tubes that are run on the cell suspensions which are to receive albumin-plasma mixture.

Adding the Untreated Saline-Suspended Cells.—

Add 1 drop of untreated saline-suspended group O Rh₁Rh₁ cells to each tube in the front row of racks 1 and 2.

Add 1 drop of group O Rh₂rh untreated saline-suspended cells to each tube of the second row in racks 1 and 2.

Add 1 drop of group O rh'rh cells untreated and saline suspended into each tube of the third row of racks 1 and 2.

Add 1 drop of group O Rh-negative cells, untreated and saline suspended, into the tubes marked for these cells, the first two or three in row 4 of the titration racks 1 and 2. If full titrations are run, there will be 10, not 2 or 3, of these tubes.

Add 1 drop of group O rh''rh untreated saline-suspended cells to each of the tubes marked for these cells (in the right-hand side of row 4 of racks 1 and 2 of the titrations). Full titrations may be run on these if desired, requiring 10 tubes, which would mean 5 rows of tubes for racks 1, 2, and 3, instead of 4 rows.

Prepare the control cell suspension tubes in rack 2, or else use a separate rack. Add 1 drop of each cell type to its respective tube. These will not receive any serum.

Preparation for Trypsinated Cell Titrations.—

In rack 3 for the titrations, add 1 drop of group O type Rh₁Rh₁ trypsinated cells to each of the front row of tubes.

Add 1 drop of group O type Rh₂rh trypsinated cells to the second row of tubes.

Add 1 drop of group O type rh'rh trypsinated cells to the third row of tubes.

Add 1 drop of group O type rh"rh trypsinated cells to the fourth row of tubes.

Add 1 drop of group O type rh trypsinated cells in the tubes marked for these cells in row 4.

Incubate all three racks, after mixing each tube, for 1 hour in a water bath at 37° C. The bath should be covered with a white cloth to keep dirt out of the tubes.

At the end of the hour, take bottom readings on the tubes, but do not disturb rack 2, which is exactly like rack 1 up to this point (except for the controls). It will be used later for the albumin-plasma mixture. It must stand undisturbed.

I. Saline Agglutination Titer.—

Read the result in each tube of **rack 1** under a scanning lens of a microscope, tilting the tube back and forth to resuspend the cells gently. The weakest dilution with a positive reaction is the titer. This gives the **saline agglutinating titer**.

II. Albumin-Plasma Titer (Wiener Test).—

Using a dropper with a fine capillary, remove all the saline from each tube in rack 2, beginning with the weakest dilution and working back to the strongest. Do not introduce any serum into the control tubes, which must be handled first. In other words, remove the saline from the control tubes, then begin with tubes 10 and remove the saline from each tube 10, then from each tube 9, then each tube 8, etc., down to tube 1.

Prepare the albumin-plasma mixture as directed above, and while the dropper (this is a second dropper) contains the mixture, add 1 large drop of the mixture into each tube in rack 2, including the controls.

Shake the rack thoroughly. Incubate at 37° C. in a water bath for 1 hour.

At the end of the hour, read under a scanning lens of the microscope, after looking at the bottoms of the tubes. Record clumping as positive and no clumping as negative.

Always read the controls first, and use the Rh-negative tubes for comparison when not sure of a negative reading.

The weakest dilution with a positive reaction is the **albumin-plasma titer**.

III. Indirect Blocking Antibody Titer (Wiener Test).—

Using rack 1, remove the saline from each tube in the front row of tubes where there is a negative reaction. If the reaction is positive, the test is not run. This test is for the "indirect blocking" reaction. Only the first row of tubes is used.

Add 1 drop of anti-Rh₀ saline agglutinating serum to each tube which shows a negative reaction, and *only to row 1 of the first rack*. This detects the Rh₀ blocking antibody.

Shake and replace the tubes in a water bath at 37° C. for 1 hour.

At the end of the hour, read under a scanning lens, and record. The last tube showing a **NEGATIVE** reaction is the titer. Explanation: In the first hour, the patient's serum was mixed with known Rh-positive cells. If these cells did not agglutinate, either the patient's serum did *not* contain bivalent (saline-agglutinating) antibodies, or else it *did* contain univalent (blocking) antibodies, which simply coated the cells but did not agglutinate them. Known anti-Rh₀ agglutinating serum was then added, which has the ability to agglutinate Rh-positive cells. Since these Rh-positive cells did not agglutinate, they must have been coated with blocking antibody derived from the patient's serum, which prevented their clumping when the known anti-Rh₀ serum was added. If they had clumped, that would indicate that there were no blocking antibodies in the patient's serum.

This gives the **indirect blocking titer**.

Fig. 254.

IV. Anti-Human Globulin Titer (Coombs Test).—

Using rack 1, add saline to each negative tube in rows 2, 3, and 4, after shaking. Fill the tubes about $\frac{3}{4}$ full.

Centrifuge and pour off the supernatant fluid, catching the last drop on a gauze pad.

Shake each tube, add saline again, and again centrifuge. This is the second washing. Remove the saline, replace with fresh saline, centrifuge, and remove saline, this time tapping the tubes hard against a gauze pad to remove all traces of saline. Take care not to lose the cells. This is the third washing.

Shake the tubes, and add a drop of Coombs serum (antiglobulin) to each tube.

Centrifuge for 2 minutes at 500 to 1,000 r.p.m. without incubation.

Read all tubes under a scanning lens of a microscope, and report clumping as positive and lack of clumping as negative. Read the controls first for comparison. The weakest dilution with a positive reaction is the **antiglobulin titer**.

This completes the tests on saline-suspended untreated cells.

V. Trypsinated Cell Titer (Morton and Pickles).—

At the end of the hour's incubation of rack 3 containing the trypsinated cells, read under a scanning lens. These tubes are handled not quite so gently as the untreated cells. Read the negative reactions first for comparison, then read the other tubes. Record clumping as positive and lack of clumping as negative. The weakest dilution with a positive reaction is the **trypsinated cell titer**.

VI. Trypsinated Cell-Antiglobulin Titer (Unger Test).—

Use all the tubes in rack 3 which give a *negative* reaction.

Wash 3 times with saline as directed above in the other tests.

After the last washing and packing, remove all the saline by tapping hard against a gauze pad, resuspend the cells, and add a drop of Coombs serum to each tube.

Centrifuge for 2 minutes at 500 to 1,000 r.p.m. and read the reactions under a scanning lens. The weakest dilution with a positive reaction is the **trypsinated cell-antiglobulin titer**.

Reactions are recorded by Unger as ++s, ++, ++w, +s, +, +w, \pm , and -.

++s means a solid clump which does not break up when being handled.

++ means not quite so solid a clump.

++w means the clump breaks up partially while handling.

The other reactions are gradations of this reaction.

Be very careful not to read false clumping due to settling of cells, or to rouleaux formation.

All trypsinated cell tubes will at first give the impression of a positive reaction, but a true positive reaction does not entirely disappear during handling. The weak ones might be difficult to read, but if they stand for a while at room temperature, the clumping returns.

The titer is the reciprocal of the last tube in which a positive reaction occurs (except in the indirect blocking reaction, where the titer is the reciprocal of the last negative reaction). See example, page 1071.

On all tubes where two tests are made, for example a Coombs test made after the saline agglutination test is negative, or an indirect blocking test after the saline test is negative, the results are recorded by Unger as follows:

- | This means the first test was negative but the second test was also negative (top result in the box).
- +| This means that the first test was negative, but the second test (antiglobulin, etc.) was positive.

NOTE: For the indirect blocking result, the box opens to the right: $\begin{array}{|c} + \\ - \end{array}$

For the antiglobulin test, it opens to the left: $\begin{array}{c} + \\ - \end{array}$

Examples: See Tables 117 A, 117 B, and 118.

O rh'rh	<u>++w</u>	<u>-</u>	<u>-</u>	<u>-</u>	<u>-</u>	<u>-</u>	<u>-</u>	<u>-</u>	<u>-</u>	<u>-</u>	1
O rh''rh	<u>-</u>	<u>-</u>	<u>-</u>	<u>-</u>	<u>-</u>	<u>-</u>	<u>-</u>	<u>-</u>	<u>-</u>	<u>-</u>	0
O rh	<u>-</u>	<u>-</u>	<u>-</u>	<u>-</u>	<u>-</u>	<u>-</u>	<u>-</u>	<u>-</u>	<u>-</u>	<u>-</u>	0

On the indirect blocking, the last **NEGATIVE** is the titer. If O Rh₁Rh₁ tubes are negative, remove saline and add anti-Rh₀ tube serum. On other negative tubes, do the Coombs test.

When negative, do the Coombs test after washing 3 times with saline.
In this example, Figs. 117A, 117B, and 118, the titers are as follows:

- 1. Indirect blocking: zero units.
- 2. Saline agglutinating: zero units.
- 3. Antiglobulin, 64 units against Rh₁Rh₁ and Rh₂rh.
- 4. Albumin-plasma method, 64 units against Rh₁Rh₁ and 128 units against Rh₂rh.
- 5. Trypsinated cell method, 128 units against Rh₁Rh₁ and also against Rh₂rh, and 1 unit against rh'.
- 6. Trypsinated-antiglobulin method, 256 units.

NOTE: If the serum gives a positive reaction against Rh-negative cells, there is an anti-hr' or anti-hr'' antibody present, or some mistake has been made.

Simplified Titration of Rh Antibodies in Serum
For Routine Hospital Use

Although the foregoing method of titration and determination of specificity gives valuable information, routinely it is not necessary to conduct all

six of the titrations. Three should suffice: the saline agglutination titration method, the antihuman globulin titration method, and the trypsin-treated cell titration method.

When Rh-negative persons are sensitized by an Rh factor, the specificity of the antibody usually involved is anti-Rh₀. Often anti-rh' is also present, and far less frequently anti-rh''. For this reason, it will suffice, for routine practice, to use untreated saline-suspended group O type Rh_zRh₀ cells and trypsinated saline-suspended group O type Rh_zRh₀ cells. Thus there will be only two rows of tubes for titrations, and, in addition, the Rh-negative controls.

Make serial dilutions as directed under the method given above: 1:1, 1:2, 1:4, 1:8, 1:16, 1:32, 1:64, 1:128, 1:256, and 1:512.

While making the dilutions place 1 drop of each dilution in its respective tube of three rows of tubes.

Add 1 drop of untreated saline-suspended group O type Rh_zRh₀ cells to each tube in the first row, and 1 drop of group O type Rh_zRh₀ trypsinated cells to each tube of the second row. In the third row, which should have 10 tubes (5 dilutions each for the negative controls), add 1 drop of the untreated saline-suspended group O rh cells to the first 5 tubes and 1 drop of trypsinated saline-suspended group O rh cells to the second 5 tubes (1:1, 1:2, 1:4, 1:8, 1:16).

Incubate all tubes for 1 hour at 37° C. in a water bath.

Read the bottoms of the tubes, and also read the reactions under a scanning lens.

Carry out antiglobulin tests on all negative reactions. Wash three times with saline. Remove all traces of saline after the last washing, using the technic outlined above.

Shake each tube and add 1 drop of Coombs serum (antihuman globulin) to each.

Centrifuge at 500 to 1,000 r.p.m. for 2 minutes, and read.

The weakest dilution giving a positive reaction is the titer. See the method above for recording the results.

Preparation of Anti-Rh Serum for Testing Purposes*

From Normal Male Donors

Owing to the difficulty of securing an adequate amount of anti-Rh serum from iso-immunized women, Wiener and Gordon¹ have suggested the manufacture of this serum by injecting normal male professional blood donors. Their theory was based upon the fact that injections of relatively minute amounts of solutions A and B group substances into individuals lacking the corresponding agglutinogens stimulated a pronounced rise in the α and β agglutinin titers in such individuals.

Their method of immunization for the preparation of anti-Rh agglutinating serum is as follows: Group O, Rh-positive blood is mixed with an equal volume of sterile citrate solution. The blood used in all experimental work belonged to type Rh_zRh_z. Four c.c. of this 50 per cent blood suspension were injected intravenously into each of a number of donors. After an interval of four months (the maximum survival time for transfused red blood cells) a second intravenous injection was given, and ten days later blood was drawn for testing. Donors with a satisfactory titer of anti-Rh agglutinins were bled.

Their original work comprised the injection of nine donors. Of these, four showed no evidence of antibody formation while five had anti-Rh agglutinins in their sera. In two donors the titers of anti-Rh agglutinins were very high, 200 and 600 units, respectively. By the method of exchange transfusion with type rh donors, 1500 c.c. of blood were drawn from each man and a satisfactory yield of testing serum was obtained.

For more recent statistics, see the Rh-Hr Types, pages 1034 ff.

*It is best to purchase these sera from U. S. Government licensed manufacturers.

Erythroblastosis Fetalis

Erythroblastosis fetalis, as stated elsewhere, may occur as a result of iso-immunization of an Rh-negative pregnant woman mated to an Rh-positive man, when the fetus is Rh-positive. Much more rarely other blood factors, Hr, Kell, etc., may produce the same effect if present in the blood of the fetus and absent from that of the mother. Two types of antibodies may be formed by the mother, "univalent,"* which are capable of passing through the placenta, and "bivalent,"* which are not. Univalent Rh antibodies, when they pass through the placenta, combine with and coat fetal blood cells for which the antibodies are specific.

The principal factor in determining the severity of the disease is the mother's antibody titer, because it in turn determines the degree of coating of the fetal cells. It must be understood that simple coating of the fetal red cells need not necessarily interfere with their function; not only must they be coated, but a third component, or "X" protein (conglutinin), must be present before clumping takes place. Although complement and complement-like substances (conglutinin or X protein) are not fully developed before birth, if the mother's antibody titer has been high for sufficient time the child may be stillborn, or, if born alive, may manifest symptoms of severe erythroblastosis fetalis. Often the baby appears normal at birth, but early in the neonatal period symptoms appear.

Treatment of the sensitized Rh-negative mother with so-called "Rh happen," diethylenesulphonate, progesterone, exchange transfusions of the mother, cortisone, "desensitizing" injections of Rh-positive blood have been unsuccessful. The only treatment which has been successful to date is the so-called "exchange" transfusion of the baby at birth before the baby's cells have had a chance to become clumped or hemolyzed (see pages 1075 ff.). In this transfusion, the baby's Rh-positive erythrocytes, as well as some plasma containing Rh univalent antibodies derived from the mother, are removed while being replaced with Rh-negative erythrocytes which cannot be coated by the offending antibodies.

The disease is characterized by abnormal destruction and regeneration of erythrocytes. It is fair to assume that intravascular clumping initiates all the other pathologic changes in this condition. Much of the pathology depends upon an excessive destruction of erythrocytes and upon an attempt on the part of the body to compensate for this loss. Anemia, increased bilirubin in the blood and in various fixed tissues of the body, abnormal erythropoiesis in many organs, including the spleen and liver, and an increase in immature forms of erythrocytes in the circulating blood are among the signs most commonly observed. (For a description of the blood picture in erythroblastosis fetalis, see page 981.) The extreme edema present in some of these cases has not as yet been explained. Some have explained it on the basis of renal failure, injury of the general capillary bed, and a decrease in plasma proteins occurring in conjunction with cellular hemolysis.

*The terms univalent and bivalent are not to be taken literally in the chemical sense but are convenient terms for designating the two forms of antibodies and for visualizing their behavior in vitro and in vivo.

There is no direct relationship between the depth of jaundice and the degree of anemia. The jaundice is hepatogenous as well as hemolytic in origin. In addition, although brain damage occurs more often in severely jaundiced babies, some severely jaundiced babies may recover completely and some with lighter jaundice die with brain damage. Wiener* believes that the tissue damage is due primarily to vascular injury resulting from intravascular conglutination of the baby's coated cells. Damage to the liver results in jaundice. Blockage of circulation in the brain produces nuclear damage and allows bilirubin to cross the blood-brain barrier and stain the dead and dying ganglion cells. Therefore, if the coated Rh-positive cells are removed before intravascular clumping occurs, and are replaced by Rh-negative cells which will not combine with the free Rh antibody, tissue damage may be prevented. Tissue damage which may be present at birth appears to be largely reversible. Kernicterus is rarely if ever found in newborn or stillborn infants. This is to some degree probably due to the fact that bilirubin formed in utero passes into the maternal circulation and is largely excreted. The rapidly developing jaundice and organic injury are probably due to increase in the concentration of complement or conglutinin in the infant's circulation during the early neonatal period. This results in intravascular clumping and hemolysis.

Sensitization to the A-B-O Factors

Halbrecht,¹ Polayes and McNally,² Wiener, Sonn, and Hurst³ called attention to cases of A-B-O sensitization, in which the Rh factor had no part whatsoever. Mild cases of erythroblastosis due to A-B-O incompatibility appear to be quite common but are usually overlooked. Most infants recover spontaneously, but in some cases the anemia is severe enough to warrant transfusion.

It was noticed first by Rosenfield⁴ that erythroblastosis due to an A-B-O incompatibility is almost always confined to group O mothers. This can readily be seen in earlier reports on series of cases by Wiener, Sonn, and Hurst, and by Wiener, Wexler, and Hurst. Wiener and Unger showed that group O babies of group O mothers acquire by placental transfer about 16 times as much isoantibody as babies having mothers of group A or group B. They concluded that this was adequate to account for the excess of group O mothers with babies having A-B-O hemolytic disease.

As explained elsewhere in this chapter (page 1000), agglutinogens A and B are both characterized by factor **C**, so that there is no anti-**C** present in the sera of groups A, B, and AB. Group O erythrocytes are the only ones which do not contain the **C** factor, and therefore, group O serum is the only variety which can contain antibodies specific for factor **C**. These antibodies, Unger and Wiener⁵ showed, are of the univalent variety, and traverse the placental barrier. Thus if the mother's blood is group O and that of the fetus is group

⁴Rosenfield, R., A-B-O Hemolytic Disease. Proc. Am. Assoc. Blood Banks, 1953: cf. Wiener, A. S., Sarnwick, A. A., Morrison, H., and Cohen, L. Exper. Med. and Surg. 11: 276, 1953.

⁵Unger, L. J., and Wiener, A. S.: J. Lab. & Clin. Med. 44: 3, 1954.

A, the fetal erythrocytes contain the **C** factor, whereas the maternal erythrocytes lack it, and anti-**C** may be formed in excess by the mother. These antibodies, in turn, traverse the placenta and enter the fetal circulation. Since these **C** antibodies cross-react with both A and B agglutinogens, if these are present in the baby's plasma in sufficient amount they may produce hemolytic disease in infants. This entire question has been discussed in detail by Unger and Wiener.⁵

In reference to these cases, Wiener⁶ concluded, first, that the A-B-O blood properties appear to be the most common cause of erythroblastosis in infants with Rh-positive mothers; second, the natural anti-A and anti-B agglutinins in maternal sera, as a rule, have little or no harmful effect on fetuses belonging to groups A, B, and AB, because they usually are of low titer and avidity and because the natural isoagglutinins presumably are larger molecular aggregates which do not traverse the placenta easily; third, individuals may become iso-sensitized against the A and B properties by the inadvertent transfusion of blood of an incompatible group, from pregnancy with a fetus of an incompatible group, or by injections of materials containing soluble group substances such as pooled human serum, therapeutic horse serum, etc.; fourth, immune isoantibodies for A and B in the maternal serum (anti-**C**) are more dangerous for the fetus than the natural isoagglutinins because they are more likely to be of high titer and, in addition, pass through the placenta more readily; fifth, cases of congenital hemolytic disease due to A-B-O sensitization are usually milder than cases due to Rh sensitization and patients frequently recover without treatment, but severe or even fatal cases, with liver damage and kernicterus, also occur and in these cases the A-B-O factors are the cause; sixth, when Rh-negative individuals are exposed to Rh-positive blood of an incompatible blood group, the principle of competition of antigens may operate, so that the agglutinogens A or B may suppress the antigenicity of the Rh factor; and seventh, in two of Wiener's cases failure to consider the possibility of A-B-O sensitization caused confusion in diagnosis, because Rh-negative mothers had Rh-positive erythroblastotic infants, yet the maternal sera did not contain Rh antibodies.

In case of pregnancy in a union between Rh-positive husband and Rh-negative wife, one may expect the first-born to be free from symptoms. Physicians should be ready to proceed with the proper treatment of children of an Rh-positive father and an Rh-negative mother by exchange transfusion with Rh-negative blood.

A-B-O hemolytic disease, in contrast to that caused by the Rh factor, frequently affects the first-born infant.

The Treatment of Erythroblastosis Fetalis by Exchange Transfusions

Wiener, Wexler, and Gamrin⁷ in 1944, adopted a method of treating erythroblastosis fetalis by exsanguination transfusion, or "exchange transfusion." This is a method of simultaneously removing the infant's blood and replacing it with other blood. In the case of Rh sensitization, Rh-negative

⁵Wiener, A. S., Wexler, I. B., and Hurst, J. G.: *Blood* 4: 1014, 1949.

⁷Wiener, A. S., Wexler, I. B., and Gamrin, E.: *Am. J. Dis. Child.* 68: 317, 1944; Wiener, A. S., and Wexler, I. B.: *J. Lab. & Clin. Med.* 31: 1016, 1946.

blood is introduced into the infant's circulation while at the same time removing the Rh-positive baby's blood containing Rh isoantibodies derived from the Rh-negative sensitized mother. The same principles apply in the cases of A-B-O hemolytic disease and isosensitization to Hr, Kell, and other blood factors.

The rationale of exchange transfusion is explained on pages 1073 and 1074. It has been known for some time that anemia is not the only cause of death in erythroblastosis, and in fact is an infrequent cause. Many babies who have been treated adequately by simple blood transfusions and even babies who have never developed any anemia rapidly have become more and more deeply jaundiced and have died on the second to fifth day of life with pathologic evidence of kernicterus, and often with liver necrosis and intrapulmonary hemorrhage. Wiener has pointed out that the immediate noxious agent in such cases is the baby's coated red cells.

There is no direct relationship between the depth of jaundice and the degree of anemia in this disease; therefore, the jaundice is not solely hemolytic in origin. Moreover, as has been pointed out above, tissue damage is due primarily to vascular injury resulting from intravascular conglutination of the baby's coated cells. Damage to the liver results in jaundice, and blockage of the circulation in the brain produces nuclear damage and allows bilirubin to enter the brain and stain the dead and dying ganglion cells. Thus it is evident that tissue damage cannot be prevented or counteracted by simple addition of blood. However, if the coated Rh-positive cells are removed before intravascular clumping occurs, and are replaced by Rh-negative blood cells which cannot be coated with the free antibody, tissue damage can be prevented.

Technic of Exchange Transfusion⁸.—

Since bleeding and administration of blood must be carried out simultaneously, total replacement of the baby's red cells cannot be attained. A pint of blood, or about twice the baby's blood volume, is used. This will accomplish 85 per cent replacement. The blood used should be less than 2 days old, and is concentrated to a hematocrit of 0.50 by removing part of the citrated plasma to the 400 c.c. mark.

Immobilize the infant on a circumcision board by the use of flannel wrappings, leaving one arm and one leg free.

Strap the leg down with adhesive tape, and expose the saphenous vein at the ankle through a transverse incision made anterior and superior to the medial malleolus.

Cannulate the vein with a blunt 20 gauge needle (a 20 gauge polyethylene catheter may also be used), and tie in place.

Inject through this needle 200 units of heparin diluted in 2 c.c. of saline.

Attach a three-way stopcock, which in turn bears the tubing from the blood reservoir and a 10 c.c. Luer-Lok syringe for the injections of the blood.

Before any injection of blood is made, isolate the radial artery through a transverse incision on the radial side of the wrist just proximal to the head of the radius. The artery can then be recognized as a moderate-sized plump vessel, the appearance and size of which are not unlike those of the saphenous vein at the ankle. There are no veins in this part of the forearm with which it may be confused. Clean the artery carefully, lift it up on

⁸Wiener, A. S., Wexler, I. B., and Brancato, G. J.: *J. Pediat.* 45: 546, 1954.

a closed mosquito clamp, and nick by placing the point of a scalpel at about the midpoint and making an angled incision through the flattened wall. The flow of blood is immediate and copious.

For convenience, collect the blood in 30 c.c. medicine glasses, and empty these into a larger graduated receptacle for final measurement. Before administering any blood at the ankle, permit 50 c.c. of the infant's blood to run out through the arterial incision.

Then commence injecting blood at a rate which keeps pace with the arterial flow, and which makes up the deficit by the time that the 90 c.c. mark is reached.

Equal quantities of blood are administered and withdrawn (about 400 c.c.), which in the average infant will effectuate an exchange of about 90%. During the procedure, administer intravenously calcium gluconate in quantities of 1 c.c. of a 10% solution for every 100 c.c. of concentrated blood given.

At the termination of the transfusion, close the incisions with fine silk sutures and apply pressure bandages. Do not ligate either the artery or the vein; it may be assumed that they recannulate in the process of healing.

Postoperatively, give the infant 100,000 units of penicillin every 8 hours for 2 days, and, if necessary, place the infant in an incubator and give continuous oxygen therapy. Feedings are routine. In instances where the procedure is repeated, use the opposite arm and leg; however, an attempt may be made to recannulate the vein (*but not the artery*) used for the first transfusion.

The small amount of heparin introduced at the beginning of the procedure facilitates the bleeding. The procedure can be carried out without heparin. Wiener and associates have never encountered any harmful effects attributable to this quantity of heparin.

The rate at which the procedure is carried out is important. The more protracted it is, the less likely it is to cause any reaction. However, it is convenient to complete the procedure in about 45 minutes; never in less than 20 minutes. At this rate, the infant can metabolize the injected citrate rapidly enough to prevent hypocalcemia. More rapid injection carries with it the danger of citrate shock.

Either freshly drawn blood or bank blood can be used, but fresh blood is safer, since the blood cells are less fragile and the danger of bacterial contamination is virtually eliminated.

If bank blood is used, it must be as fresh as possible, preferably not more than two or three days old. For concentrated blood, use sedimented bank blood. All that is necessary is to aspirate the supernatant citrated plasma down to the 400 c.c. mark. This should be done immediately before use, the bottle inverted, and a sample withdrawn, centrifuged, and examined for hemolysis by observation of the supernatant plasma. A stained film is made for examination for bacterial contamination.

When these precautions are observed, the procedure is virtually without danger. If any difficulty is encountered with infusion, numerous other sites are available.

The umbilical catheter method of Diamond is not recommended since it has been said to have caused damage to important intra-abdominal vessels with resultant thrombosis and embolism. Intra-abdominal hemorrhage, peritonitis, and splenic rupture have also been reported following its use. There is also the danger of direct injection of citrated blood into the heart chamber.

Titration of Anti-A and Anti-B Antibodies in Serum for the Detection of Isosensitization in Erythroblastosis Fetalis, Method of Unger Modified After Wiener et al.

In cases of erythroblastosis fetalis or in sensitization unexplained by the Rh-Hr factors, it is necessary at times to titrate the anti-A and anti-B antibodies. With ordinary methods of titration, it is not possible to differentiate between natural and artificially produced anti-A and anti-B antibodies. This method attempts to make the differentiation.

Acacia.—

Dissolve 20 gm. acacia (gum arabic)
and 2 gm. Na₂HPO₄ (dibasic sodium phosphate)
in 180 c.c. of distilled water.
Autoclave at 10 pounds pressure for 10 minutes.
Use the supernatant fluid.

Cells.—

Use A₁ rh cells suspended in saline for titrating anti-A in group O or group B serum.
Use B rh cells for titrating anti-B in group O or group A serum.

Prepare the cells in the usual manner, wash once with saline, and resuspend to a 2 or 3% concentration in saline. See page 1006.

Titration for Bivalent Antibodies.—

Make serial dilutions of the serum to be tested, in saline: 1:1, 1:2, 1:4, 1:8, 1:16, 1:32, 1:64, 1:128, 1:256, 1:512. See page 1015 for exact technic.

Add 1 drop of the opposing cells to 1 drop of each dilution of serum (see page 1015).
Carry out two titrations on group O serum, one using A₁ rh and one using B rh cells.

Incubate in a water bath at 37° C. for 1 hour.
Take bottom readings and also read under a scanning lens.
Report clumping as positive and lack of clumping as negative.
Record the result in each tube.

Acacia Conglutination Titer.—

To each negative tube, add 1 drop of the acacia solution.
Mix and incubate in a water bath at 37° C. for 1 hour.
Read as before. Report the results. This gives the acacia conglutination titer.

Titration for Univalent Antibodies.—

At the same time, run titrations on the same serum diluted 50% with Witebsky group specific substance (1:2).

Carry out the titrations exactly as directed above, and report results in the same manner.

If there is a titer in this second set of tubes, the antibodies are due to isosensitization by A-B-O factors, since ordinarily Witebsky substance neutralizes bivalent anti-A and anti-B antibodies. Apparently it does not neutralize the univalent antibodies.

Examples: For examples, see Table 119.

TABLE 119

DILUTIONS:	1:1	1:2	1:4	1:8	1:16	1:32	1:64	1:128	1:256	1:512	TITER

<i>Same Serum, Witebsky Substance Added, No Acacia</i>											
1. A ₁ Cells	—	—	—	—	—	—	—	—	—	—	No titer
2. B Cells	++s	++	++w	++w	+w	—	—	—	—	—	1:16
<i>Same Serum, Witebsky Substance Added, Acacia Suspended Cells</i>											
1. A ₁ Cells	++	++w	+s	+w	—	—	—	—	—	—	1:8
2. B Cells	++s	++	++w	++w	+s	+w	—	—	—	—	1:32

Conclusions:

- (1) There is a 1:64 anti-A titer for bivalent antibodies.
- (2) There is a titer of 1:8 for univalent anti-A antibodies when acacia is used in the titration, but no univalent antibody titer when using saline-suspended untreated cells.
- (3) The anti-B titer for bivalent antibodies is 1:128, and 1:256 when acacia (conglutinin) is used.
- (4) The univalent antibody titer is 1:16 for anti-B for untreated cells, but 1:32 when acacia is added.

At birth, anti-A and anti-B are from the mother. All anti-A and anti-B antibodies later developed by the individual are probably of heterospecific origin.⁹ The titration described here is used to differentiate between bivalent and univalent antibodies. This patient has been isosensitized against A and B factors, and has univalent antibodies in the blood. If this has occurred in unexplained erythroblastosis fetalis, this individual is sensitized to the A-B-O factors and not the Rh-Hr factors.

Summary

1. Rh₀ agglutinogens are found in 85 per cent of Caucasoids and are absent in 15 per cent. The 85 per cent are called **Rh₀**-positive and the 15 per cent, **Rh₀**-negative. About 2 per cent of all bloods contain **rh'** or **rh''** or both, without the **Rh₀** factor. Such people must be given Rh-negative blood in a transfusion, but their blood can be safely given only to Rh-positive patients.

2. The injection of Rh-positive blood into an Rh-negative person, as in blood transfusions, may stimulate Rh antibody formation which in itself is not harmful provided no further transfusions are made. In the case of Rh-negative women in the child-bearing age, this antibody formation might lead to an erythroblastotic infant if the woman is mated to an Rh-positive man.

3. Injection of one dose of Rh-positive agglutinogens into an Rh-negative person starts a chain of immune body production. If a second transfusion of Rh-positive blood is made in an Rh-negative person already immunized with one Rh-positive injection, hemolytic reaction is almost certain to occur. This is serious and at times fatal.

4. The mating of an Rh-positive man to an Rh-negative woman may produce offspring that have been subjected to changes, either death in utero or a living child that soon after birth develops erythroblastosis fetalis. This does not always occur with the first child except in cases of Rh-negative women previously isoimmunized by an Rh-positive blood transfusion.

5. Treatment of erythroblastosis fetalis by exchange transfusion at birth, using Rh-negative blood, is the proper procedure. If no Rh-negative blood is available, the washed cells of the mother may be used.

6. All patients and all donors must be subjected to a test for the Rh factors.

7. In all pregnancies, particularly where the mother is Rh negative and the father is Rh positive, sensitization tests must be made periodically of the mother's serum, and if antibodies are found, titrations must be made at frequent intervals. If the titer is rising, one must be prepared to perform an exchange transfusion immediately if the infant is born alive. See page 1063.

Agammaglobulinemia

Inhibition Test for Human Gamma Globulin, Method of Wiener^{1, 2}

Agammaglobulinemia was first described as a syndrome by Bruton,³ and later elaborated by Bruton and associates.⁴ Patients with agammaglobulinemia show complete or almost complete absence of antibodies from their serum, rendering them susceptible to recurrent infections. Their serum lacks the normal blood group isoagglutinins, as well as gamma globulin as detected electrophoretically. The other serum proteins may be within normal limits.

A test for agammaglobulinemia was devised by Wiener,¹ based on the ability of antihuman globulin sera prepared in rabbits to agglutinate human red cells coated with antibodies of human origin, such as Rh antibodies and autoantibodies. Since materials containing human gamma globulin can inhibit the reactions of such antiglobulin sera, this inhibition technic has been applied to detect the presence of human gamma globulin in patient's serum. The test can be performed quantitatively² by testing a series of progressively doubled dilutions of the material in question, at the same time carrying out parallel titrations with normal human serum as a control.

The sensitivity of the inhibition test for gamma globulin is inversely related to the titer of the antiglobulin serum used. If a low-titered serum is used, the inhibition titer will be high; the higher the titer of the antiglobulin serum, the lower the gamma globulin inhibition titer. Thus if the test is performed qualitatively only, the diagnosis of agammaglobulinemia could be missed.

Principle.—

The solution to be tested for the presence of serum globulin is mixed with absorbed antihuman globulin serum (diluted to have a titer of 10 to 20 units for maximally coated Rh-positive cells) and the mixture allowed to react in a water bath at 37° C. for one hour. Then a suspension of Rh-positive cells, coated with **Rh₀** univalent antibody, is added, and the mixture allowed to stand for a second period of incubation, after which the reaction is read. Failure of clumping to occur indicates the presence of human serum globulin in the material being tested. Occurrence of clumping indicates the absence of human serum globulin.

Reagents.—

Preparation of Rh Sensitized Cells.—

Prepare a 2% suspension of **Rh₀**-positive cells in saline.

Wash once with saline solution and resuspend to 2% concentration.

Mix with an equal volume of **Rh₀** antiserum containing univalent antibodies with a titer of approximately 100 units by the albumin-plasma method (page 1069).

Allow the mixture to react in an incubator at 37° C. for 45 minutes.

Centrifuge at moderate speed.

Discard the supernatant fluid.

Wash the sedimented cells 4 times with large volumes of saline.

Resuspend sensitized cells to an approximate 2% suspension in saline.

Antiglobulin Serum.—

Antiglobulin serum used for the test can be purchased from most institutes which manufacture blood grouping sera. It is commonly referred to as "Coombs serum." It

²Wiener, A. S.: *Am. J. Clin. Path.* 25: 595, 1955.

³Bruton, O. C.: *Pediatrics* 9: 722, 1952.

⁴Bruton, O. C., Apt. L., Gitlin, D., and Janeway, C. A.: *Am. J. Dis. Child.* 84: 632, 1952.

is absorbed according to the requirements of the NIH before being packaged. This is diluted so as to have a titer of 10 to 20 units for the Rh-sensitized cells.

Technic.—

Prepare serial dilutions in saline of the serum to be tested and of normal serum in the same manner as for titrations, as given on page 1015. Use dilutions of 1:1, 1:2, 1:4, 1:8, 1:16, 1:32, 1:64, 1:128, 1:512, etc.

Place 1 drop of each dilution in its respective small Kahn tube, properly labeled.

Add 1 drop of the diluted antihuman globulin serum to each.

Incubate at 37° C. in a water bath for 45 minutes.

Add 1 drop of Rh-positive sensitized cells to each tube.

Shake the tubes and reincubate for 60 to 90 minutes in a water bath at 37° C.

Shake gently and read the reactions macroscopically over a lighted viewing box and under a scanning lens of a microscope.

Results.—

Normal human adult serum completely inhibits agglutination in dilutions as high as 1:500 on the average, depending on the titer of the antiglobulin serum.

Normal human spinal fluid in Wiener's experiments inhibited the antiglobulin serum from reacting in dilutions of approximately 1:2 or 1:4, but this was expected because normal spinal fluid contains only about 30 mg. per cent of protein in contrast to the 7 gm. of protein found in normal human serum. Saliva showed inhibition ability to a slight degree; umbilical cord serum inhibited antiglobulin serum to the same titer as adult serum. Serum from horse, ox, and rabbit did not inhibit antiglobulin serum, and rhesus monkey serum weakened its reaction.

In cases of congenital agammaglobulinemia, inhibition titers of about one-fiftieth the normal titer were obtained. This indicates the presence of only 20 to 30 mg. of gamma globulin per 100 c.c. of serum in such individuals rather than a complete absence of gamma globulin. Following treatment with gamma globulin there is a corresponding increase in the inhibition titer.

Witebsky Substance, or A and B Group Specific Substance*

The chemical nature of the A specific substance has been investigated by Landsteiner,¹ Landsteiner and Chase,² Landsteiner and Harte,³ Meyer, Smyth, and Palmer,⁴ Goebel,⁵ Freudenberg and Westphal,⁶ and several others. These investigations confirm the work of Brahn and Schiff,⁷ Freudenberg, Eichel, and Dirscherl,⁸ and Landsteiner,⁹ who first isolated an A specific carbohydrate-like substance from horse saliva in 1932. The study of the A substance is facilitated by its occurrence in relatively large amounts in commercial preparations such as pepsin and peptone.

*Witebsky substance is now available from Sharp and Dohme, Philadelphia, Pa.

Witebsky and Klendshoj¹⁰ reported a study of the nature of group specific B substance. They isolated it from stomach juice of group B subjects, shown to be rich in group specific substances. This isolation was carried out by Witebsky and Klendshoj very much like that in which Goebel⁵ isolated the A substance from commercial peptone. They found this group specific B substance in human stomach juice, determined that it was carbohydrate-like, and that it was as potent as the carbohydrate-like substance group A isolated from commercial pepsin and peptone, respectively.

Witebsky, Klendshoj, and Swanson¹¹ attempted to reduce or eliminate the anti-A and anti-B agglutinins in O blood by addition of solutions of "A" and "B" specific substances. As Ottenberg¹² first pointed out, the presence of the isoagglutinins anti-A and anti-B in the donor is at times ignored because of the dilution to which the serum of the donor is subjected in the case of a blood transfusion. Usually 500 c.c. of blood are given to adults in one blood transfusion. The resulting dilution is about 1:10 to 1:15. It is obvious that isoagglutinins present in O blood having a higher titer than 1:15 might act upon the recipient's cells if these cells contain A or B isoagglutigen. It is likely, however, that group substances¹³ in the blood as well as in the tissues capable of combining with isoantibodies represent a factor which, in addition to the dilution factor, is responsible for the fact that the isoantibodies in O blood do not produce more damage than has been reported when group O is used as a "universal donor."

For the preparation of the group substance A, commercial peptone and pepsin are used since these have been found to contain large amounts of A. The source of the group substance B is not stated by Witebsky. Witebsky found that the A substance, when isolated from peptone, forms a whitish powder which readily dissolves in water. He made up a stock solution of 1:1,000 in salt solution and used this in all of his experimental work.

Goebel Technic.¹⁴—

Four hundred fifty grams of peptone (Difco neopeptone) and 180 gm. sodium acetate ($\text{CH}_3\text{COONa} \cdot 3\text{H}_2\text{O}$) were dissolved in 1,350 c.c. of water, and the crude fraction containing the A substance was precipitated by the addition of 3,375 c.c. of 95% alcohol. The precipitate was collected in centrifuge tubes the following day and redissolved in 270 c.c. of water. Undissolved sediment was discarded after centrifugalization. The insoluble fraction was collected again after addition of 45 gm. of sodium acetate and 675 c.c. of alcohol. This procedure was repeated a third time using 150 c.c. of water and 24 gm. of sodium acetate and precipitating with 2.5 volumes of alcohol. The precipitate was redissolved in 180 c.c. of water, and 27 gm. of sodium acetate were added. The pH of the solution was adjusted to 4.8 by the addition of 20% acetic acid. This solution was deproteinized by shaking for 16 hours with a mixture of 40 c.c. of chloroform and 8 c.c. of butyl alcohol according to Sevag's procedure. The resulting solution gave negative tests for protein with 20% trichloroacetic acid, 5% sulphosalicylic acid and saturation with picric acid. The fraction containing the A substance was recovered from this solution by precipitation with 2.5 volumes of 95% alcohol. A solution of this substance in water was dialyzed through Cellophane against successive changes of distilled water.

¹²Ottenberg, R.: *J. Exper. Med.* 13: 425, 1911.

¹³Wiener, A. S.: *Blood Groups and Blood Transfusion*, ed. 2, Charles C Thomas, footnote p. 55.

¹⁴Goebel: *J. Exper. Med.* 68: 221, 1938.

The solutions were kept in the refrigerator during dialysis. The active fraction was finally precipitated in 10 volumes of acetone. The substance tends to remain in colloidal suspension but forms a flocculent precipitate quite readily after the addition of a few crystals of sodium chloride. The precipitate was collected on a hardened filter paper, washed with acetone, and dried over sulphuric acid.

It was found by Witebsky that the A specific substance displayed a marked inhibitory influence on the agglutination of human blood cells of group A by serum of group B. A 1:250 dilution of his stock solution completely inhibited agglutination under the particular experimental conditions chosen, while some inhibitory influence was detectable even in dilutions of one in several millions. This A specific substance when dissolved in physiologic saline solution was markedly heat stable.

He showed the lack of toxicity of this substance by experimental work on guinea pigs. In further experimental work, he showed that no agglutination of human red blood cells of group A by plasma of group O occurred when the dilution of the plasma was as much as 1:256 or more. It is believed that the addition of A substance to O bloods is harmless and simultaneously effective by reducing the titer of the anti-A agglutinin present in O blood to such an extent as to render it practically ineffective.

In a further communication, Witebsky, Klendshoj, and Swanson¹ gave specific directions for the preparation and transfusion of safe universal blood. They called attention to an amendment to the Sanitary Code of the State of New York adopted by the Public Health Council June 26, 1940, requiring group O blood to be titrated before it is used as universal blood with a high titer of isoagglutinins. Gesse² described 46 cases of hemolytic shock following the transfusion of universal blood, 20 of which caused death of the patient. On the basis of these investigations, he formulated the following three postulates: (1) Not more than 100 to 200 c.c. of universal blood should be transfused; (2) the number of erythrocytes and the hemoglobin content in the blood of the recipient must be determined. Transfusion of universal blood is permissible if the number of erythrocytes is above 2 million. (3) The titer of the donor's blood serum toward the erythrocytes of the recipient must be determined. Only the blood of a universal donor with a titer of as low as 1:8 to 1:16 can be used.

In spite of these postulates, Gesse warns against the use of the blood of a universal donor unless, in a case of real emergency, homologous blood is not available. He opposes the use of universal blood on a large scale under war-time conditions.

Witebsky discussed his work, previously reported,³ on the use of the A specific substance added to O blood to eliminate the anti-A antibody.

The addition of the isolated group specific substances A and B caused a reduction in strength, or even elimination of the antibodies anti-A and anti-B present in the so-called universal blood of group O. Universal blood conditioned by the addition of group specific substances can be given to any patient independently of the blood group to which he belongs without the neces-

¹Witebsky, E., Klendshoj, N. C., and Swanson, P.: *J. A. M. A.* **116**: 2654, 1941.

²Gesse, E. R.: *Deutsche Ztschr. f. Chir.* **245**: 371, 1953.

³Witebsky, E., Klendshoj, N., and Swanson, P.: *J. Infect. Dis.* **67**: 188, 1940.

sity of previous determination of the patient's blood group in emergencies even without cross-matching. This blood, when kept in blood banks, is available for immediate use.

Blood group specific substances A and B are now available from Sharp & Dohme, Philadelphia, Pa., who prepare this substance in 10 c.c. sterile vials. The contents of one vial (10 c.c.) are added to 500 c.c. of group O blood.

Tisdall, Garland, and Wiener¹ showed that there is definite danger in stimulating increased antibody formation in female patients potentially capable of childbearing. For this reason, one must be careful about transfusing such women with group O blood modified by group specific substances. Certainly, however, in the face of an emergency, there should be no hesitancy in using such blood. There is also danger of stimulating antibody formation against factors as yet undiscovered.

Commenting upon this entire question, these writers believe that the use of universal donor group O blood will still play an important role in transfusion work but that group O blood must have a low titer of isoagglutinins to be safe for use as universal donor blood.² Such a low titer will mean discarding about 25 to 50 per cent of group O bloods to be used for this purpose. In the presence of a large demand for universal donor blood, such a waste of material would be unwarranted. Based on observations made in their study, it was felt that the routine addition of A and B substances to group O blood would render any group O blood perfectly safe for use as universal donor blood for military purposes. The other therapeutic role of universal donor blood is its use for the immediate treatment of emergency cases of hemorrhage in civilian life. Low titer group O blood should be transfused while proper groupings and cross-matching tests are being carried out. As an additional precaution, Rh-negative blood should be used. Because of the impracticability of having two kinds of universal donor blood, one for men and one for women, they believe that low-titer group O blood destined for use as universal donor blood in civilian hospitals should be selected according to the technic outlined in their previous paper,² without the addition of A and B substances. Their conclusions in the entire matter are presented as follows:

1. As little as 25 c.c. of a group B plasma containing a high titer of isoagglutinins caused a hemolytic reaction when administered to a group A recipient.

2. A and B group specific substances will reduce a high isoagglutinin titer to low levels.

3. Experiments on the administration of plasma with high titers of anti-A agglutinins to group A recipients present definite evidence that the addition of group specific substances A and B is a safe and reliable method for preparing all group O blood for use as universal donor blood for military purposes.

4. A and B substances are capable of antibody stimulation even when in combination with the anti-A and anti-B agglutinins of group O blood. This calls for some caution in administering such material to women potentially capable of childbearing.

¹Tisdall, L. H., Garland, D. M., and Wiener, A. S.: *J. Lab. & Clin. Med.*, 31: 437, 1946.

²Tisdall, L. H., Garland, D. M., Szanto, P. B., Hand, A. M. and Bonnett, J. C.: *Am. J. Clin. Path.* 16: 193, 1946.

5. For use as universal donor blood in civilian hospitals, Rh-negative group O blood, selected for its low natural isoagglutinin titer, is somewhat preferable to random group O blood to which group substances have been added to reduce the isoagglutinin titer.

Summary of Procedures Necessary in Carrying Out a Danger-Free Test of Donor and Recipient for Blood Transfusion Purposes*

1. Use highly potent anti-**A** and anti-**B** sera which meet the requirements of the National Institutes of Health (N.I.H.). Never use pooled sera of unknown titer, and under no circumstances use leftover sera from the serology laboratory just because they are anti-**A** or anti-**B**.

2. Keep known group A and group B blood on hand for controls. These may be taken as small clots, or they may be collected in the special anticoagulant.

3. Have on hand reliable absorbed anti-**A** serum to differentiate the subgroups A_1 from A_2 , and A_1B from A_2B .

4. Have on hand anti-**Rh**₀, anti-**Rh'**₀, and anti-**Rh''**₀ slide test sera and also anti-**Rh**₀, anti-**rh'**, and anti-**rh''** (tube) saline agglutinating sera.

5. It is well to have the anti-**Hr** sera which are available.

6. Test unknown cells against anti-**A** and anti-**B** sera, running controls at the same time.

7. Test unknown sera against known A and B cells for confirmation of blood group.

8. Subgroup all A's and AB's.

9. Test for the **Rh**₀ factor in whole blood of patients.

10. Test for the various Rh factors in whole blood of donors.

11. Cross-match in test tubes the donor's cells with the patient's serum and the patient's cells with the donor's serum. If negative, do the anti-globulin test. If positive before or after the antiglobulin test, reject the donor.

12. At the same time, do sensitivity tests on patient's and donor's sera for Rh antibodies. Do not use any donor blood which contains such antibodies.

13. Group O Rh-negative donors can be used in emergencies for post-partum cases and in retransfusions, particularly if the supernatant plasma has been removed.

14. Whenever a patient's serum shows presence of Rh antibodies, titrate to determine the concentration.

15. Whenever the donor is Rh-negative by the slide test, perform the tube test.

16. In all unexplained cases of erythroblastosis fetalis, test for other blood factors and also titrate the anti-**A** and anti-**B** antibodies.

NOTE: If a PATIENT'S blood lacks **Rh**₀, consider this patient Rh negative and give only Rh-negative (type rh) blood, even though patient's blood contains factor **rh'**, **rh''**, or both.

If a DONOR'S blood lacks **Rh**₀, but contains **rh'**, **rh''**, or both, consider this donor Rh positive, and give this blood only to Rh-positive patients. Or, better, make a tube test to determine the exact Rh type.

*See pages 1008 ff.

The Choice of Donors

The choice of donors is very important. The proper group should be selected, of course, as determined by the tests just given. In addition, the donor must be in good physical health and able to stand the withdrawal of 500 c.c. of blood without injuring his health. In many communities, donors are selected, physically examined, grouped, and kept on call whenever blood transfusions are needed.

Syphilis and Blood Transfusion.—The donor must be free from acute or chronic disease, more especially must it be proved as accurately as possible that he is not suffering with active syphilis. It is necessary first to conduct a physical examination and, second, to perform a serologic test. A complement fixation test or the VDRL test may be performed. Possibly, for rapid results, the Kline test is the method of choice. In the Continental countries, the Sachs-Georgi and the Meinicke methods are very popular. These are precipitation tests similar to our Kline test in this country. It must be remembered, however, that a negative Wassermann reaction is not complete proof that the donor is free of syphilis. A positive reaction, however, is sufficient to reject a candidate for donor for blood transfusions.

There are more than sixty-eight cases on record in which syphilis has been communicated to the recipient because of the use of a syphilitic donor's blood. Wildegans¹ details a case of a transfusion on a case of hemoptysis, in a 33-year-old man who showed, ten weeks after the transfusion, widespread syphilitic skin eruption where the donor's blood Wassermann had been negative. How many other cases have occurred and have not been reported is a matter of speculation. Moritsch and Wittman² in Vienna detailed a case in which syphilis was transmitted from a donor who had a negative Wassermann test. In this case the donor was later proved to have had a primary syphilitic manifestation at the time of the transfusion, but sufficient time had not elapsed for him to show a positive Wassermann reaction. In another case reported by Bernheim, a syphilitic son, acting as donor, communicated syphilis to his father. In this case it was not thought necessary to perform a Wassermann test. Levy and Ginsburg³ reported a similar case. Feldmann reported from Moscow, U.S.S.R., an infection from transfusing the blood of a nurse into a recipient. Nineteen days before the transfusion, a negative Wassermann had been obtained on this donor. Other cases have been reported by Dufur, Brehm, and Cordiviola.

In these cases, the syphilitic infection is transmitted directly into the blood stream without the development of any primary manifestation. As a rule, the incubation period of this blood-transmitted syphilis is from four to ten weeks. It is usually followed by a vigorous and typical roseola (*Syphilis d'emblée*).

McNamara⁴ reported eleven cases of syphilitic infection in blood transfusion where a mistake had been made in the blood reports. White reported similar cases. A positive syphilis reaction should be sufficient for rejection of a candidate as donor.

Professional and voluntary blood donors, who may be exposed to infection with syphilis during intervals between transfusions, should have serologic tests made for syphilis prior to every blood transfusion regardless of the frequency of the donations and the relation of the recipient. For instance, Périn and Lefèvre⁵ reported the transmission of syphilis from mother to child by blood transfusion. As pointed out by Rein, Wise, and Cukerbaum,⁶ in their statistical survey, "The Control and Prevention of Transfusion Syphilis," blood donors' promises and assertions of noninfection cannot be depended upon and should not be taken seriously. They emphasize, too, that the Kline exclusion test is so highly sensitive that when the reaction is negative it usually excludes syphilis. It has been shown by the United States Public Health Service⁷ that the more reliable flocculation tests were specific to the same degree and more sensitive than the complement fixation tests. The committee expressed the opinion that "certain tests which may be performed rapidly on blood specimens appeared to yield results comparable to those obtained with tests requiring a longer period for their performance." The above scientific survey suggested that the following procedure be made prior to all transfusions:

- A. Establish the blood group of all volunteer donors and regroup all professional donors.
- B. Determine the suitability of the donor's blood for the recipient by cross-matching.
- C. Detect the presence of syphilis serologically by means of the very sensitive and specific Kline diagnostic and exclusion flocculation tests.
- D. Detect any clinical evidence of syphilis by means of an adequate physical examination.

Later Morgan⁸ reviewed 16 cases of indubitable transfusion syphilis, Salkind⁹ 39 cases, Klauder and Butterworth¹⁰ 35 cases, and Eichenlaub and Stolar¹¹ 41 cases. Since this last communication, seven additional cases have been recorded.^{12, 13, 14, 15, 16, 17} Among the total reported cases, in at least ten instances blood was transfused from a donor who was in the incubation period of the disease, i.e., before the appearance of a primary lesion or the development of a positive serologic test, and in at least nine other instances the donor was in the sero-negative phase of the primary stage of syphilis. Another patient was infected by a donor who had recently been treated for early syphilis and who at the time of the transfusion had a negative serologic test. In these twenty transfusions routine serologic examination of the donor's blood therefore did not disclose the presence of the infection.

With the advent of blood banks, this problem has been greatly simplified, because of two reasons: (1) ample time is available for carrying out tests for syphilis prior to using the blood; and (2) blood stored at icebox temperature

for 72 hours is possibly incapable of transmitting syphilis even though obtained from a donor whose freshly drawn blood is infectious. In this connection, Turner and Diseker¹ report their interesting experiments on the duration of infectivity of *Treponema pallidum* in citrated blood stored under conditions obtaining in blood banks. They added *T. pallidum* to citrated blood from both human beings and rabbits, and determined the infectivity of the mixture for rabbits after various periods of refrigeration. Blood from syphilitic rabbits known to be in an infectious stage was likewise tested. Blood from human beings with early syphilis was not tested because even under the most favorable conditions rabbits are infected with difficulty with such material. Results obtained with a strain of *T. pallidum* well adapted to the rabbit were regarded as being a more reliable index of survival or death of the organism than would be the results obtained with freshly isolated strains. Their experiments showed that, under the conditions obtaining in blood banks, syphilitic spirochetes probably undergo progressive deterioration during the storage period. Even when large numbers of virulent treponemata were added to citrated whole blood the mixtures were not infectious for normal rabbits after storage for three days or longer. After storage periods of one and two days, although viable organisms were still present, they were evidently considerably reduced in numbers or in virulence, since the incubation period of the lesions resulting from the inoculation of the same amounts of the stored mixture was significantly prolonged, and in some instances, the inoculated animals escaped infection. These experimental observers believe that the infectivity of syphilis treponemata in citrated whole blood rarely persists for longer than three days at refrigerator temperature.

Bloch² obtained infection with material stored for 72 hours. Survival for 96 hours was not demonstrated. Bloch's conclusions were that there is definite risk of transmitting syphilis to the recipient of blood from patients with early syphilis if the blood has been preserved for 72 hours or less in the blood bank. Though this risk probably diminishes rapidly after 96 hours, it would still be unwise to use the blood from persons with known early syphilis.

These experimental observations confirm the statements made above and should cause one to pause in listening to speculative platitudes from those uninformed in experimental data that syphilitic blood when stored is safe and can be given with impunity. The axiom that no syphilitic blood should ever be given in transfusion, whether fresh or stored, still obtains.

Professional donors should carry a book in which is inscribed the name, residence, age, result of serologic test, and the blood group. Each withdrawal of blood should be entered in this book, together with the date.

The question of just when blood can safely be taken from the same person the second time has been much discussed. The rate of hemoglobin regeneration in blood donors has been studied by Fowler and Barer. Previous investigations by Giffin and Haines,³ who studied 84 donors, many of whom had given blood for twenty or more transfusions, indicated that donations of 500 c.c. of blood at intervals of four to five weeks are not harmful to male donors but that in female donors anemia often develops under similar conditions. Martin and

¹Turner, T. B., and Diseker, T. H.: Bull. Johns Hopkins Hosp. 68: 269, 1941.

²Bloch, Oscar: Bull. Johns Hopkins Hosp. 68: 412, 1941.

³Giffin, H. Z., and Haines, S. F.: J. A. M. A. 81: 532, 1923.

Myers¹ expressed the belief that blood should not be taken more frequently than every three months. They noted, too, that hemoglobin regeneration is slower in female than in male donors. Fowler and Barer observed 200 blood donors who had given blood for 636 transfusions at the University Hospitals in Iowa City. These were mostly young people. They found the average drop in blood hemoglobin after the removal of 555 c.c. of blood was 2.3 gm. and the average time required to replace this amount of hemoglobin was 49.6 days. The longer recovery periods were associated with a greater drop in hemoglobin and could not be correlated with the initial blood hemoglobin values. With a smaller donation and a smaller drop in the blood hemoglobin, the recovery period was shorter. Hemoglobin was regenerated in men at the rate of 0.049 gm. per hundred cubic centimeters of blood per day under these conditions, and in women the increase was 0.040 gm. per day. It is their opinion that subsequent donations may be given with safety as soon as the blood hemoglobin has returned to its original level. An interval of six weeks should be allowed between blood donations provided that at that time the hemoglobin of the donor has returned to normal. They found that the administration of 1 gm. of iron and ammonium citrates per day increased the daily hemoglobin regeneration by 49 per cent and shortened the recovery period from 49.6 to 35.2 days during the first period of its administration. It had progressively less effect after subsequent blood donations.

WHOLE BLOOD TRANSFUSION

The principal indication for transfusion of whole blood is sudden loss of blood from hemorrhage. Such cases call for immediate transfusion of whole blood.

In addition to acute loss of blood, consideration must be given to the hemorrhagic states which call for transfusions. There are two significant factors in the body's defense against hemorrhage:² (1) coagulability of the blood and (2) vascular response. Among the conditions representing defective coagulating mechanism are hypoprothrombinemia, thrombocytopenia, hemophilia, and fibrinogenopenia. Refer to pages 1114 to 1121 for discussion of the use of plasma in peripheral circulatory failure or shock. The preoperative preparation and postoperative care of patients call for transfusions when there is impaired nutrition, secondary anemia, dehydration, and lowered resistance. Transfusions for these purposes are done almost routinely in many institutions as a preoperative procedure. In hypoproteinemias, the use of plasma is preferred over whole blood or, better, an initial injection of plasma followed by an injection of whole blood.

Splendid results in whole blood transfusion during World War II have been outlined by Agress.³ As Chief of the Laboratory Service of the 21st General Hospital (Unit from Washington University, serving in North Africa, Italy, and France), Agress was in a very fortunate position to observe the effects of whole blood transfusion in the wounded in order to put them in the

¹Martin, J. W., and Myers, J. T.: *J. Lab. & Clin. Med.* 20: 593, 1935.

²Kilduffe, R. A., and DeBakey, Michael: *The Blood Bank and the Technique and Therapeutics of Transfusions*, St. Louis, 1942, The C. V. Mosby Co.

³Agress, Harry: *Washington Univ. Med. Alumni Quart.*, Jan., 1946.

proper condition for operation and rapid convalescence. He found that the use of the copper sulphate technic of Phillips, Van Slyke, and associates for determining hemoglobin, hematocrit, and total proteins lent itself to measuring the blood status of the patients. It was found by this test that many of these patients had low blood values on admission to the hospital. Of 4,404 patients, 64 per cent showed a deficit in either hemoglobin or total blood proteins, or both. The main deficiency was in hemoglobin. Only 11.4 per cent had subnormal protein concentrations, that is, less than 6 grams per cent in the blood. When the percentage of patients showing subnormal concentrations of blood proteins was plotted against the hematocrit or hemoglobin concentration, a most important relationship presented itself. (See Fig. 255.) As the deficit

Fig. 255.—(From Agress, Harry: Washington Univ. Med. Alumni Quart., Jan., 1946.)

in hemoglobin became more marked, the percentage of patients showing a diminution in blood proteins rose; at a level of 40 volumes per cent in the hematocrit only 2.3 per cent of the patients had protein levels below 6 grams per cent, but at a level of 30 volumes per cent in the hematocrit, 38.7 per cent of the patients had subnormal protein concentrations. Whipple³ has demonstrated that the body "guards jealously the fabrication of hemoglobin and given a real need for both plasma protein and hemoglobin, the protein flow favors hemoglobin synthesis, which under these circumstances is always produced in more abundance than plasma proteins." Accepting the finding of Whipple, it is self-evident that the correction of the anemia in a great percentage of military patients was imperative, if they were to be converted from the traditionally poor surgical risks to better prospects for surgery. Agress

³Whipple, G. H.: Am. J. M. Sc. 203: 477-489, 1942.

called attention further to the observations of Elman⁴ that many patients have approached protein depletion long before the concentration of total proteins in the blood has become subnormal. He also suggested the importance of ingested protein on the status of body proteins and speaks of depletion of protein resulting from "acute protein starvation." In the injured soldier there is protein starvation inherent in the traditional management of the surgical patient. The gaunt appearance of many of these patients made this fact self-evident. Lyons called attention to this nutritional depletion and stated that weight losses varying from five to thirty kilograms had been observed in wounded soldiers. Agress properly assumed that in the therapeutic approach to these patients correction of anemias as a means of restoring more normal blood relationships is urgent. He treated these patients with as much blood as was necessary to restore the hemoglobin to normal instead of waiting for the slow process of spontaneous hemoglobin synthesis, usually aided and abetted by foodstuffs, iron, or blood in minimal quantities. Hemoglobin is not supplied by plasma. By giving adequate amounts of blood, the hemoglobin hunger of these patients was appeased and great progress was made in restoring normal physiologic relationships. When hemoglobin deficits were quickly restored, the patients were transformed from poor surgical risks to excellent ones. In his hospital experience in the military zones where he served, shock was practically nonexistent after the institution of the program of using large amounts of whole blood.

How much blood is needed? Five hundred cubic centimeters of whole blood were required for every increment of 3 volumes per cent deficit in hematocrit below 45 volumes per cent in order to restore normal hemoglobin values. The progress of the blood status of each patient was followed by serial copper sulphate determinations and adjustments in the amount of blood given made according to the results of these follow-up studies. Almost unheard of quantities of blood were used. For instance, during the twelve-month period preceding the reparative surgery program in his hospital, Agress stated that 213 transfusions were given. For a similar period of time during which the program was in effect, 9,619 transfusions were given, despite the fact that the surgical admissions were only one and one-half times those of the previous period. One patient required as many as sixty transfusions.

These facts are quite interesting and important in civilian as well as in military practice. It is obvious that not enough whole blood is being given to patients preparatory to surgical operation. It is recommended that the copper sulphate method be used as outlined by Agress in civilian surgery preparatory to operation and that adequate amounts of whole blood be utilized. Often too little whole blood is given to patients and equally often too much is unnecessarily given.

In addition to the hemorrhagic states, transfusion of whole blood is necessary in anemias of blood loss, anemias with increased erythrocytic destruction of hereditary or acquired nature. The basic principle of blood transfusion utility in anemia is a replacement therapeutic procedure. The usefulness of transfusions in anemias due to increased destruction or excessive hemolysis of erythrocytes is seen in the good results in familial hemolytic jaundice,

⁴Elman, R.: *Ann. Surg.* 120: 350-361, 1944.

sickle-cell anemia, erythroblastosis, and many acute and chronic types. There are other types of anemia where blood transfusions are welcome; namely, Cooley's erythroblastic anemia.

Transfusions are indicated in leukemia, although no particularly brilliant results are seen in the chronic leukemias except, perhaps, relief of the associated anemia. In regard to leukopenia, the rationale for transfusion is only of a supportive nature. According to Doan,¹ transfusion is proper in neutropenic states because normal blood contains nucleotides which stimulate the formation of these neutrophilic cells. Transfusions have been used in agranulocytosis with varying success in different hands.

In infections, blood transfusions have been used in many acute and chronic conditions. Small multiple transfusions have been used in infections with good results. In intoxications and poisoning, whole blood transfusions have been valuable; plasma injections, however, have been even more useful.

The **contraindications for blood transfusions** are principally acute pulmonary edema, cardiac decompensation, and massive pulmonary embolism or infarction.

Heparin and Transfusion.—The Scandinavians have been using heparinized blood in transfusions for a number of years. It eliminates the disadvantages of sodium citrate as an anticoagulant and greatly simplifies the procedure of transfusion when given directly to the donor. It may be added to the donor's blood in vitro or injected into the donor during the technic of transfusion.

The Direct Method of Blood Transfusion.—There are various methods of making a direct blood transfusion dependent upon the type of apparatus used. The first modern method for blood transfusion using an apparatus was the one described by Unger.² This apparatus permitted the withdrawal of blood from the donor and the simultaneous injection of saline into the patient. A stopcock was then turned and the reverse situation resulted; blood could be injected into the patient and saline simultaneously injected into the donor. It was this immediate flushing with saline of that part of the instrument not used for the aspiration or injection of blood that insured freedom from clotting.

Another method is that using multiple glass syringes. In this method, there is a battery of about twenty 20 c.c. glass syringes. These are sterilized and placed on a sterile table close to the donor. An assistant inserts a needle into the donor's vein and the operator inserts a needle into the recipient's vein. The first 20 c.c. syringe is half filled with warm saline, that is, about 10 c.c., and 10 c.c. of blood are withdrawn. The syringe is quickly disconnected and connected up with the needle in the recipient's vein and the first syringe material is injected. While this is being injected, the assistant takes the next 20 c.c. syringe and fills it up with blood, passes it to the operator who in turn injects it. In this way, the operation is carried out and the operator, by counting the number of syringes alongside his table, sees at all times just how many cubic centimeters of blood he has injected.

Indirect Method of Blood Transfusion

The best method of indirect blood transfusion is one which makes use of vacuum bottles, a closed circuit to prevent bacterial contamination, and disposable tubing, needles, and other equipment. Such equipment is manufactured by Baxter Laboratories, Inc., Morton Grove, Ill., and also by Abbott Laboratories, Chicago, Ill., and Cutter Laboratories, Los Angeles, Calif. The Baxter equipment is described here. See Fig. 256.

Fig. 256.—Transfuso Vac containers. Blood collected in these containers may be stored up to 21 days and administered as whole blood, or plasma may be prepared from the stored blood. The remaining cells may be used for red cell infusion. Capacity of containers are, from left to right, 150 c.c., 250 c.c., 1,000 c.c., 500 c.c. (Courtesy Baxter Laboratories, Inc., Morton Grove, Ill.)

The use of rubber tubing in blood transfusion is now obsolete. We have therefore eliminated all reference to directions for cleaning and sterilizing such tubing. Since some institutions still use the metal valve instead of a completely disposable unit, directions for using this valve are included in this chapter.

Directions for Obtaining Blood, Using a Metal Valve

Remove the expendable Baxter Transfuso donor set from its sterile wrappings.

Close the sterile valve by turning the knob clockwise. Fig. 257 shows the Transfuso Valve.

Fig. 257.—Baxter Transfuso Valve. (Courtesy American Hospital Supply Corporation, Chicago, Ill.)

Tear the metal seal from the Transfuso-Vac, lift off the metal disk, and remove the top plastic diaphragm aseptically. Fig. 258.

Insert the needle of the Transfuso Valve perpendicularly through the sealing diaphragm and stopper at point marked "X" on the top of the Transfuso-Vac. Immediately after insertion, recheck the valve to make certain it is still closed.

Attach the disposable tubing and needle.

Choose the vein to be used and carefully prepare the overlying skin with iodine. Make compression on the upper arm, preferably with a blood pressure cuff, and insert donor needle into the vein.

Open the valve slightly by turning the knurled knob counter-clockwise.

While the blood is flowing, agitate the Transfuso-Vac to mix the blood and citrate and prevent coagulation.

When the desired amount of blood has been drawn, close the valve. Remove the blood pressure cuff, withdraw the needle from the vein. Remove the valve from the Transfuso-Vac and salvage the blood from the tubing for serologic study by opening the valve and allowing the blood to run into the sterile pilot tubes, one with and one without anticoagulant. Shake the tube containing the anticoagulant.

Fig. 258.

Fig. 259.

Fig. 258.—Closure of Transfuso-Vac and Plasma-Vac containers. Note the metal identification disk under which is a plastic disk which protects sterility, and a thin rubber disk to protect the surface of the stopper. (Courtesy Baxter Laboratories, Inc., Morton Grove, Ill.)

Fig. 259.—Baxter blood and plasma container stopper. The puncture position is marked with an "X." This thicker portion of the stopper will reseal after use so that the vacuum is retained after the blood unit is filled. (Courtesy Baxter Laboratories, Inc., Morton Grove, Ill.)

Agitate the Transfuso-Vac a minimum of 3 minutes, assuring adequate mixing of the citrate and blood, thus safeguarding against clotting.

Before placing the filled Transfuso-Vac in a refrigerator overnight (as for the preparation of plasma, etc.), break the remaining vacuum with a sterile air filter. This is a needle connected with a piece of rubber tubing to a glass outlet containing cotton, the entire apparatus having been previously sterilized by dry heat.

To Clean the Transfuso Valve.—

Remove the valve stem. Do not remove the valve nut and needle in cleaning. If needle replacement is necessary, be sure to replace the nut tightly. Remove any residual clots which may remain in the valve needle or valve proper by loosening with a stylet from a 15 gauge needle.

Wash thoroughly in a solution of tincture of green soap. If clots remain, immerse in concentrated ammonium hydroxide for 10 minutes and then rinse in triply distilled water. Never use tap water to wash the valve.

Reassemble, using a liberal quantity of U.S.P. glycerin in the grooves of the valve stem and on the threads of the valve barrel.

Leave the Transfuso Valve one-quarter open during autoclaving. If a valve "freezes," return it to the manufacturer for repair.

Rinse with 5 to 10 c.c. of sterile saline to remove any water which, if it remained, would cause hemolysis.

Wrap and sterilize in an autoclave at 15 pounds pressure for 20 minutes.

Fig. 260.—Making venepuncture for collection of blood, using Baxter Transfuso-Vac with sterile expendable Plexitron R20A blood collection set. (Courtesy Baxter Laboratories, Inc., Morton Grove, Ill.)

Fig. 261.—Blood collection nears completion. (Courtesy Baxter Laboratories, Inc., Morton Grove, Ill.)

TO WITHDRAW BLOOD USING DISPOSABLE UNITS

Prepare the donor as above. To obtain blood, proceed as above, except that no valve is needed if the Transfuso donor set of the expendable type is used. Method of using such sets is shown in Figs. 260 and 261.

To obtain blood for blood grouping and other serologic tests, clamp the Plexitron tubing with the aluminum disk, release tourniquet, withdraw needle from the rubber stopper, insert into vacuum pilot tubes, one of which contains a dry anticoagulant, and remove enough blood from the donor's vein to fill the tubes about three-quarters full. Then clamp the tubing, withdraw the needle from the vein, and cleanse the skin in the usual manner. Shake the tube containing the anticoagulant.

TO ADMINISTER WHOLE BLOOD

Invert the Transfuso-Vac momentarily to moisten the hole in the rubber stopper. With a pair of sharp scissors, cut the rubber diaphragm at the extreme edge, farthest from the air tube.

Tear the diaphragm straight across, exposing both holes in the rubber stopper.

Place the aluminum disk (control clamp) on the Plexitron tubing, Fig. 262, of the administration set, Fig. 263.

Insert the drip device of Plexitron R18 administration set into the bottle of blood, suspend the bottle by its bail, and fill the drip device with blood as shown in Figs. 264 and 265.

Fig. 262.

Fig. 263.

Fig. 262.—Aluminum disk, used as a control clamp for administering blood, plasma, serum, etc. The flow of fluids can be accurately controlled. The disks are used once and then discarded. (Courtesy Baxter Laboratories, Inc., Morton Grove, Ill.)

Fig. 263.—Sterile expendable Plexitron R18 set for administering blood, plasma, or serum. (Courtesy Baxter Laboratories, Inc., Morton Grove, Ill.)

Establish the blood level in the drip device, then open the clamp to fill the remainder of the set and to remove all air from the tubing.

Attach the vein needle to the Nylon needle adapter and again be sure that there is no air in the needle or the tubing.

Make puncture of the patient's vein in the usual manner after disinfecting the skin, and proceed with the transfusion.

Adjust the clamp to control the rate of blood administration (Fig. 266).

If one desires to start the transfusion with saline or to mix saline with the blood, or to follow the transfusion with an injection of saline, connect the Transfuso-Vac to the bottle of sterile saline, connecting them with a "Y" outfit leading into a filter drip. This "Y" outfit is also a disposable unit. See Figs. 267, 268, 269.

SUGGESTED AND ACCEPTED PROCEDURES

Some such acceptable technic as tincture of iodine and alcohol should be vigorously used in preparing overlying skin. Site for insertion is then anesthetized by an injection of 1 or 2% Novocain intradermally. Place blood pressure cuff on donor's arm, setting the pressure at slightly below diastolic level. Insert needle in donor's vein through anesthetized skin with bevel of needle up.

Fig. 264.—Drip device of Plexitron R18 administration set is filled with enough blood to cover the filter by “milking” the rubber tip. (Courtesy Baxter Laboratories, Inc., Morton Grove, Ill.)

Fig. 271.—Baxter Plexitron R48 combination administration set and pressure pump, which enables administration of blood at the normal rate or rapidly under pressure. The rate of administration is determined by pumping action. The R48 *cannot pump air*, since it operates with fluids. It contains a filter that permits rapid administration through mesh fine enough to remove particulate matter. (Courtesy Baxter Laboratories, Inc., Morton Grove, Ill.)

Fig. 272.—Aspirating plasma. The plasma will be drawn off into a vacuum container. (Courtesy Baxter Laboratories, Inc., Morton Grove, Ill.)

If blood does not flow immediately, close Transfuso Valve (or clamp if disposable unit is used) and improve position of needle. Improper placement of needle may cause collapse of tubing. It will be expanded again by flowing blood when needle is properly placed in vein. This is a good check on needle position. When blood is flowing freely the Transfuso Valve or clamp is slowly opened further and the flow of blood gradually increases until desired rate is established. Average rate is between 75 and 125 c.c. per minute.

Usual causes of insufficient flow of blood are:

- a. Needle is not in good position in the vein.
- b. Pressure in the blood pressure cuff is too high or too low. Occasionally, a better flow can be maintained if donor slowly opens and clenches hand.

Note: If it becomes necessary to remove needle from vein always close valve before removing needle. After the needle has been removed from the vein, hold it as high as possible above valve and very slowly open the Transfuso Valve allowing blood remaining in tubing to be drawn into Transfuso-Vac. Instantly close valve when blood is entirely out of tubing. Re-insert donor needle and slowly re-open Transfuso Valve, so as not to collapse vein.

Blood From Cadavers for Transfusion

Considerable interest was evoked by the announcement of Judin, chief surgeon of Sklifasovski Emergency Hospital in Moscow, who within 3 years performed more than 300 blood transfusions, taking the blood from dead individuals, storing it, and then injecting it into living patients. Judin's work has been referred to by Gosset, chief surgeon of Salpetriere Hospital in Paris, in a publication entitled "La Transfusion du Sang de Cadavre a l'Homme."

In Moscow whenever an acute accidental death occurred from suicide, homicide, or in an industrial accidental way, the dead subjects were immediately brought to one hospital where their entire venous blood was removed and stored. The cadaver was strapped on his back on the operating table, covered with sheets and sterile drapings, just as would be done in the case of a major operation on the living. The neck was left exposed and prepared with sterile precautions, iodine and alcohol, etc. The jugular vein was exposed and two slits made into the vein, one for a cannula to receive blood from the head, the other from blood below. These cannulas were connected with glass sections and rubber tubing, terminating in sterile glass jars stoppered with cotton. No citrate was added. The blood clotted, was placed in a refrigerator, and within two hours the blood was fluid. The clots had autolyzed. The operating table was tipped forward at a sharp angle and blood permitted to flow by gravity into the jars. The filled jars were kept at refrigerator temperature just one or two degrees above freezing point, and warmed in a water bath at 40° C. just before use.

Judin has kept this blood as long as a month and used it without reaction. Kahn and complement fixation tests are run on the specimens before use.

According to this account of Judin's work, the blood of many cadavers has been tested and found sterile. Of course, the subjects used are persons who have died suddenly, from accidents, suicide, or heart attack. It is claimed that all fresh blood from this type of death is free from bacteria. This raises a question in my mind, for in 1904, I¹ reported an account of a research upon this very question; namely, does the blood of cadavers meet-

¹Gradwohl, R. B. H.: Ann. Inst. Pasteur 18: 766, 1904.

ing death from acute accident or from a sudden illness, contain bacteria? This was in reply to a publication of Simmonds² who claimed that in a bacteriologic examination of the cardiac blood of 1,200 subjects, he found a streptococcus in 95 per cent of all cases, autopsy being performed from twelve to thirty-six hours after death. Canon³ later claimed that Simmonds' work was in error in that cardiac blood alone was examined and that if at the same time venous blood had been examined, it would have been found that venous blood was sterile, even with streptococci in the heart blood. Our own work was undertaken in an attempt to settle this point, and so fifty cases were selected from our service at the Coroner's office in this city, in the main, gunshot wounds of the chest, fractures of the skull, ten cases of valvular leak, three cases of rupture of aortic aneurysm, six cases of nephritis, a few cases of purulent peritonitis from abortions, etc. The time elapsing from death to the moment of autopsy performance varied in our cases from as little as two hours to as long as ten hours. In 78 per cent of these cases, bacteria of various kinds were found in the cardiac blood, in only three cases were bacteria found in blood from the median basilic vein. The bacteria found were streptococci, staphylococci, *Proteus vulgaris*, *Escherichia coli*, pneumococci, pyocyaneus. We concluded that there is a rapid invasion of the cardiac blood soon after death, from neighboring organs, and that bacteriologic results therefore from cardiac blood in the cadaver must be weighed in the balance before being accepted as causative factors in deaths of such cases.

These findings give us pause in accepting this Russian announcement, which, while emphasizing that the blood from the jugular veins is free from bacteria, still does not take into account that blood drainage in Judin's technic, coming from the region of the heart as well as from other parts, makes it possible to introduce these postmortem invaders into the recipient end of the transfusion. Further research should be conducted to determine the possibility of infection in such a technic. It is an interesting communication, however, and deserves study and investigation, for even with our best methods in the modern hospital, sometimes very valuable time is lost in finding a donor for an urgent and almost exsanguinated individual. The modern blood bank should supplant this Russian procedure.

Blood Banks

The so-called "blood bank"^{4, 5} was first established in Russia, but the first in America was at the Cook County Hospital, Chicago, Ill. It was eminently successful and has been adopted in many other places. It is essentially a method of keeping on hand quantities of blood so that the hospital is always prepared to give blood transfusions. Like all banks, it is supposed to be operated on the principle that withdrawal of blood means substitution of other blood, so that the supply on hand is fairly constant. A blood bank is a useful adjunct for an institution, provided it can afford equipment and personnel.

²Simmonds: Virchows Arch. 175: No. 3, 1904.

³Canon: Centralbl. allg. Path. u. path. Anat. 15: 133, 1904.

⁴Fantus, B.: J. A. M. A. 109: 128, 1937; Modern Hospital 50: 57, 1938.

50: 57, 1938.

⁵Fantus, B.: J. A. M. A. 111: 317, 1938.

For the satisfactory operation of a blood bank, equipment and personnel are required. Unless it is under the control of responsible personnel and continuously checked, it is obviously a dangerous addition to any hospital program.

Blood is obtained from the relatives and friends of patients who are transfused. There must be direct contact with the donors. Donors should be between the ages of 21 and 60; in good health; should be free from syphilis as proved by serology and physical examination; chronic alcoholics should be rejected; there should be a history of no recent illness, mild or severe. Donors who meet these requirements must certify in writing that they release the hospital from all liability and they must give permission to use blood as the hospital authorities may elect. The rules governing a donor clinic are as follows:

1. Those in charge must be well trained and well supervised.
2. Simple, uniform technic must be used.
3. Unusual care must be taken in technic to preserve product.
4. Discomfort of donor must be reduced to minimum.
5. Adequate room must be provided and unnecessary delay avoided.

The practice is to draw blood from all donors without preliminary typing or testing. This is deposited in favor of the patient for whom it was given. That means that each transfused patient has an account and he may receive blood until his account has been exhausted. If any patient has more than is needed, this may be transferred to the account of some patient who lacked donors. Withdrawing blood from all donors who volunteer prevents the necessity of taking large amounts from any one person. All samples must be thoroughly tested before being used.

The next step in blood banking is storage of blood in the refrigerator, which is carried out immediately, as undue exposure to room temperature and unnecessary handling cause hemolysis. The optimum storage temperature is 4° C. with a permissible range of temperature from 2 to 6° C. Citrated blood will freeze between 0 and -1° C. Attachment of the refrigerator to an electric circuit separate from that of all other electric appliances is advisable so that current failure will not so quickly occur.

A refrigerator has been devised with a "refrigerator indicator" attached to each flask to indicate whether or not refrigeration has been properly observed during the history of the blood specimen. DeGowin and Hardin⁶ have advised two types of refrigeration indicator and label employing 13 by 100 mm. Pyrex glass tubes and a mixture of oleic and palmitic acids with a melting point of approximately 50° F. or 10° C. In type I the fatty acid mixture is colored with Sudan III. The glass capillary tube is filled with the red liquid at room temperature, chilled to freeze the mixture, and threaded on a card label through which holes have been punched. Melting of the mixture causes it to be lost from the tube. Type II employs uncolored fatty acids separating two glass beads. The melting of the mixture allows approximation of the beads.

According to Kilduffe and DeBakey,⁷ two such indicators were preferred. The first is a mixture of 96 per cent oleic acid and 4 per cent palmitic acid, by

⁶DeGowin, E. L., and Hardin, R. C.: *War Med.* 1: 334, 1941.

⁷Kilduffe, R. A., and DeBakey, A. B.: *The Blood Bank and the Technique and Therapeutics of Transfusions*, p. 234, The C. V. Mosby Co., St. Louis, Mo., 1942.

volume, which has a melting point between 10 and 13° C. This mixture is poured at room temperature into a 13 by 100 mm. serologic test tube to a depth of 1 cm. and a red or blue glass bead is added, which sinks to the bottom. The mixture is then solidified by plunging the tube in an ice bath and a similar glass bead is placed on top. The tube is then tightly corked and attached to the blood flask by a rubber band. A slip of cord or heavy paper showing the source and date of the blood collection can also be inserted into the tube. During storage, if the temperature rises to the melting point of the solidified fatty acids, the glass bead on the surface sinks, and the presence of both beads together at the bottom indicates refrigeration failure, in which case the flask should be discarded. The second type of indicator described by these authors utilizes the same fatty acid mixture colored by the addition of Sudan III. At room temperature the liquid mixture is sucked up into a 3 cm. length of glass tubing of 4 to 5 mm. diameter. The mixture is then frozen solid by immersion in ice water, the tube is threaded through two holes of a label card, and the card is inserted into a previously chilled 13 by 100 mm. test tube, which is then corked and attached to the blood flask. As contact between capillary tube and test tube is prevented by the label card, a layer of air insulation is thus provided. If failure of refrigeration allows the temperature to rise to the melting point of the fatty acid mixture, after ten to twelve minutes the red mixture runs out of the capillary tube.

The blood is checked daily by the banker for evidence of hemolysis. The equipment for procuring blood is essentially the same as that described for blood transfusion. Blood is dispensed daily during the regular banking hours except for emergency transfusions. Request to the laboratory to determine the type of the patient is made and request, with patient's blood, is sent to the bank, where cross-matching is done. All blood in the blood bank should have been previously grouped and subgrouped, including the Rh type.

Blood should be transfused immediately. It should be handled not more than is necessary. An intern should remain with the transfused patient for the first fifteen minutes. All reactions should be reported to the Director of the blood bank service. All reports of transfusions should be returned to the blood bank within twelve hours after transfusion.

It must be repeated here that all blood in the blood bank should be proved to have come from nonsyphilitic and nonmalarial patients. Routine culture tests should be done to detect bacterial contamination.

No blood should be used that has been kept longer than three weeks. Outdated bloods may be used to procure plasma, following the practice of removing plasma from the whole blood as outlined on page 1122. In addition, the red cells may be saved for use in special medical and surgical conditions.

In connection with the question of blood banks, attention is to be called to the following section contributed by the American Red Cross on the American Red Cross Blood Program. This program was instituted in this country to provide blood transfusions for the smaller hospitals which cannot afford to conduct a blood bank of their own. There are now forty-five Regional Centers.

American Red Cross Blood Program*

The American Red Cross had its first experience in blood procurement during World War II when it collected approximately fourteen million pints of blood which were turned over to commercial laboratories for processing for the Armed Forces. The Red Cross served only as a collection agency; all other processes were carried out either by the Army or Navy or by laboratories under contract to them. Following World War II, the Red Cross expected to get out of the field of blood collecting and did. However, technical advances made during the war increased the demand for blood, particularly by physicians who had had both blood and plasma and occasionally serum albumin available. Because of this demand some Red Cross chapters were permitted to operate so-called "walking blood banks" on a community basis; others operated collection centers. Although these permissive programs served a need in limited areas, the need for blood was critical in many others. Upon the request of the Army and Navy, Veterans Administration, American Hospital Association, American Medical Association, U. S. Public Health Service, and other allied organizations, the Red Cross investigated the possibility of a national blood program.

With the endorsement in principle of its program, the Red Cross opened its first Regional Blood Center in Rochester, N. Y., in January, 1948. The St. Louis Center was the twelfth to open. Its opening date was August, 1948. There are now 45 Regional Centers. Fifteen Defense Centers came into being for the collection of plasma after the Korean conflict began.

A Regional Center opened in a particular metropolitan area after receiving approval of the American Hospital Association, Catholic Hospital Association, any hospitals not belonging to either, Medical Society, Public Health Service, and the Red Cross Chapter in that city and those in the surrounding areas expecting to be served by mobile units. Defense Centers opened with the same approvals plus an understanding that blood collected by these centers would not be distributed to hospitals in the area but would either be used as whole blood in Korea or processed by commercial laboratories as plasma, serum albumin, or immune globulin for the Armed Forces. Blood quotas of approximately 5 per cent of the population per year were set for Regional Centers and about half that for Defense Centers.

The original aim of the Red Cross Program was to make blood and blood derivatives available to all whenever and wherever needed. It was realized by those outlining the program that this ambitious aim could be reached only through complete cooperation of the American public, which really is the American Red Cross. Cooperation had to come through many channels; first, people must be donors so that the product would be available; second, hospitals and doctors must be willing to use blood in a highly intelligent and conservative manner; third, technical personnel must be willing to learn enough about blood to be able to administer it with the least amount of hazard. Hospital administrative people, technicians, nurses, Red Cross personnel had to be able to explain the simple operating details of the program to recipients.

*This section has been prepared by the St. Louis Regional Blood Program, American Red Cross, St. Louis, Mo.

These details are primarily concerned with why the administration charge is made and what it covers, why some hospitals continue to operate their own blood banks and receive little Red Cross blood, and why some hospitals receive their total supply from Red Cross, and other such questions.

The technical problems have been well handled by physicians and laboratory technicians. Those not previously accustomed to having blood available have sought and obtained the necessary information for safe administration. In explaining the technical aspects of the program, we must pay tribute to the outstanding experts in American medicine who outlined the technical operation of the program and who continue to give it direction. The official Medical Advisory Committee of the Red Cross Blood Program is the same as the Blood and Blood Derivatives Committee of the National Research Council. This

Fig. 273.—In a Red Cross Blood Center, a nurse replaces her equipment after taking a pint of blood from a donor. A Red Cross volunteer nurse's aide lends assistance.

committee participated in the writing and approved the technical manual used by the various centers. The technical operation of each center has the approval of the National Institutes of Health and has a yearly inspection. The technical aspects of the program may be divided into four units for the sake of discussion: donor requirements and acceptance; collection technique; laboratory work; and distribution.

Donor requirements may be divided into those requirements set up for the protection of the donor and those requirements set up for the protection of the recipient. We will consider first those **requirements protecting the donor**:

Age.—Persons between the ages of 18 and 59 are acceptable; persons from 18 through 20 must have written parental permission unless married and then the written permission may come from the spouse.

Temperature and Pulse.—Temperature and pulse are checked and any abnormalities are reported to the attending physician.

Weight.—Donors must weigh at least 110 pounds.

Blood Pressure.—In general, persons with systolic pressures between 100 and 200 are acceptable. The physician checks on the medical history of some in this group and may reject them on his findings.

Hemoglobin.—12.5 grams per 100 c.c. for women and 13.5 grams for men is considered the lowest level for acceptance. Those falling below this level are rejected by the physician. The hemoglobin test is made by the Phillips and Van Slyke copper sulphate specific gravity technic. A disposable lancet is used in pricking the finger. All lancets and needles used are of the disposable type in order to eliminate the danger of transmitting homologous serum jaundice from one donor to another.

History.—

In order that no one ill of some acute disease or chronic illness be taken as a donor, each donor is asked questions concerned with the following conditions: illness in past month, surgical operations in past six months, tuberculosis, diabetes, rheumatic fever, cardiovascular disease, kidney disease, persistent cough, pain in chest, shortness of breath, fainting spells, and convulsions. Any person giving a positive answer to any of these questions is automatically referred to the attending physician who accepts or rejects him on an individual basis. Extreme apprehension is occasionally the cause for rejection. The physician makes an attempt to give the prospective donor a good understanding of why he is rejected, whether or not he may give blood at another time, and what course to follow.

Briefly, the points for consideration for **protection of the recipient** are:

Blood or Plasma Transfusion.—No donor is accepted who has had a blood or plasma transfusion in the past six months.

Malaria or Antimalarial Therapy.—Donors who have had a history of malaria or who have received intensive suppressive therapy but who have had neither a clinical attack nor suppressive therapy in the preceding two years may be accepted for donations to be used as whole blood. Donors who have had neither a clinical attack of malaria nor intensive suppressive therapy in the past six months may be accepted for donations to be used as plasma or plasma fractions only.

Undulant Fever.—Persons having had undulant fever within the past two years are rejected. If the disease occurred more than two years ago the donor is acceptable.

Jaundice.—Persons having had infectious hepatitis or homologous serum jaundice within the past two years may not be donors. Persons having had contact with either disease in the past six months may not be donors. This blood shall be clearly marked for derivatives only.

The problem of contact with homologous serum jaundice and infectious hepatitis presents a real problem when considering laboratory technicians, nurses, physicians, and other hospital personnel as donors. There have been

many recent reports of "needle jaundice" in persons doing venepunctures and examining the blood of patients. We would like to caution all laboratory personnel that the greatest of care should be exercised to protect themselves from infection by the blood of any patient. Any break in the skin should be carefully protected.

Allergy, Asthma, and Hay Fever.—The transmission of nonspecific antibodies by stored blood does not present the great problem that it does in fresh blood; nevertheless a person who feels well but gives a history of recent allergic manifestations is accepted for plasma or derivatives only.

Immunizations.—In general, a person may give blood two weeks after receiving immunizations. If a shorter interval intervenes, the blood will be marked for plasma.

Fig. 274.—Technician in the laboratory of the St. Louis Regional Blood Center making blood grouping tests, including the Rh factor. This is a mass operation. There were 410 blood specimens on the day the photograph was taken; each two represent a blood donor. In the background can be seen tubes lined up for the confirmatory tests using serum against known A and B cells.

The actual collection technic depends to a degree on the type of equipment used. At the present time, all venepuncture sets and bottles used are of the disposable type made by commercial houses. Whole blood collections are taken in bottles containing 110 c.c. of acid-citrate-dextrose (ACD) solution. Blood for plasma is taken in bottles containing 50 c.c. of 4 per cent sodium citrate. The rubber stopper is prepared with 2 per cent aqueous iodine and 70 per cent alcohol before insertion of needle. The arm preparation is done with 50 per cent aqueous green soap, 2 per cent aqueous iodine removed with 70 per cent alcohol. Intracutaneous 1 per cent procaine is injected before the venepuncture is performed if the donor requests it. Bleedings for ACD and citrate are done in 5 to 7 minutes. Blood collected in ACD is care-

fully agitated approximately five times during withdrawal and is thoroughly shaken after withdrawal is completed. Blood taken in citrate is not agitated unless separation of blood from anticoagulant is noted. Immediate refrigeration is instituted in both cases.

We shall outline the procedures as carried out by the St. Louis Regional Blood Program. Blood collected in ACD solution is distributed only after the following laboratory work has been done:

1. Determinations of A-B-O groups by known sera and known cells.
2. Determinations of the Rh factor, **Rh₀** (D), **rh'** (C), and when sera are available, **rh''** (E).
3. Serologic test for syphilis is the VDRL.
4. Titrations have been discontinued on all group O donors. Group O, ACD bottles are labeled "Isoagglutinin Titer Not Determined." We discourage the use of group O blood as universal donor blood, but realize that in cases of extreme emergency it must be used. Titrations should be carried out in hospital laboratories if group O blood is to be used as universal donor.

A-B-O grouping and Rh tube typing tests are made on blood taken in sodium citrate solution. All other laboratory work is performed in the commercial laboratory.

The A-B-O groupings and Rh typings are done by the slide method from clotted samples collected at the time of venepuncture. A Clay-Adams viewer is used for the Rh tests. Commercial sera of a potency meeting National Institutes of Health standards are used.

Although the standard three-tube Kahn is used for the serologic test for syphilis in some Red Cross Blood Centers, many others are converting to the VDRL syphilis test. Donors with positive tests are followed up as recommended by the State Health Department.

The laboratory procedures are of the simplest type commensurate with the greatest accuracy possible. Perhaps the greatest problem for new personnel and a continuously troublesome problem for the experienced technician in mass typing is that of keeping all determinations related to one unit of blood carefully identified. The elimination of the human error in mixing samples and numbers relating to samples must be accomplished. In American Red Cross Blood Centers, we have found the use of one number to identify a given sample and the use of one laboratory worksheet with no copying to be most helpful in preventing the most common errors in transcribing. "Reverse grouping" using unknown sera plus known A and B cells (2 per cent) is made as a check against the original grouping tests. The value of two technicians reading the same test cannot be overemphasized.

Labeling, storage, and distribution of blood is the final unit for consideration. Every bottle is properly identified as to contents, including the formula of the anticoagulant, date of expiration (21 days from collection for ACD), name and address of collecting agency, results of laboratory tests, i.e., serology, grouping, and typing. A whole blood number corresponding to that on the donor's medical history card appears on the bottle label and can be used to trace any unit of blood to the donor. Each ACD bottle has a pilot tube of

clotted blood taken at time of venepuncture securely taped to it. This tube is taped to the bottle prior to the venepuncture and is not removed at any time in the Center.

Blood is stored in a temperature of 4° to 6° C. in a refrigerator used for this purpose only and which has a constant recording device and alarm system.

The blood is distributed by the American Red Cross in precooled iced cases.

Untoward Reactions Following Blood Transfusions

Up to the time of the appearance of the publications of Landsteiner,¹ there had been repeated grave manifestations of agglutination and hemolysis from the mixture of incompatible bloods. His work, showing the blood groups of human beings, laid the foundation upon which has been built the present relatively safe and secure method of blood transfusion as it is practiced today. Reactions sometimes occur due to errors in blood grouping and the consequent transfusing of blood of an incompatible group. Wiener et al.* discussed their experience with reactions in more than 3,000 transfusions. They divide transfusion reactions into two main groups; first, those due to some specific incompatibility between the blood of the patient and that of the donor, and, second, those due to nonspecific agents, the latter constituting the vast majority.

Attention has frequently been called to the danger of using group O indiscriminately as a universal donor because of an occasional hemolytic reaction. Levine and Mabee pointed out that in group O donors with high isoagglutinin titers the dilution of donor's serum in the patient's circulation might not be sufficient to prevent hemolytic reaction; in fact, cases have been reported of hemolytic reactions following use of such dangerous universal donors. It is reasonable to believe that such instances of reactions are certainly high when universal donors are used routinely. It is known that group O is characterized by its incompatibility with A and B.

The work of Wiener and Peters and Levine has shown that the Rh agglutininogen with its consequent anti-Rh agglutinin development is definitely a factor which causes many reactions in blood transfusions. This has been fully explained on pages 1024 ff. In other words, the Rh intragroup isoimmunization must be taken into account to explain the reactions that occur in pregnancy from using an Rh-positive donor for an Rh-negative patient. This also explains the reactions in repeated transfusions where Rh-positive blood is injected into Rh-negative individuals.

The so-called "hemolytic" reaction may occur after the administration of a small amount of blood but usually occurs after introduction of 50 c.c. or more of blood. Such patients complain of tingling sensation or a sense of great discomfort and anxiety, fullness in the head, precordial oppression or a constricting feeling in the chest and difficulty in getting their breath, and severe pain in the back of the neck and the chest and especially in the lumbar region. Signs of collapse follow with rapid feeble pulse, cold clammy skin, marked flushing of the

face, dyspnea, cyanosis, drop in blood pressure, dilatation of the pupils, and nausea and vomiting. Hemoglobinuria frequently develops with anuria and jaundice later.

It has been said that the commonest cause of fatality in blood transfusion is introduction of incompatible blood. Death in these cases may be due to multiple thromboses, including the capillaries, but sometimes death occurs due to exsanguination because of the hemorrhagic tendency following a hemolytic reaction. It is, however, manifest that the most common fatal mechanism after the injection of incompatible blood is the comparatively slow and undramatic onset of renal insufficiency. This is accompanied by anuria and uremia and is always of the gravest importance. The mechanism involved in the suppression of renal function after hemolytic transfusion reactions is not settled. Experimental work by many writers has shown that precipitated hemoglobin does block the tubules in these cases, but, in some cases of fatal transfusion anurias, there is no such tubular obstruction. This matter has been well discussed by Peters,² who reported a case of anuria following hemolytic reaction to blood transfusion, with recovery following splanchnic block. He discussed the various theories of pathologic changes in the kidneys and noted that the kidneys of patients dying of transfusion anurias often present points of similarity to the kidneys observed in the so-called "reflex anurias," in which latter vasoconstriction plays such an important part. It is to be noted that not only has renal vasoconstriction been experimentally produced by intravenous hemoglobin injection, but also in the comparatively few reported autopsies after transfusion anuria, the kidneys are grossly congested and swollen. Wiener³ declares the kidneys are usually found to be swollen, with the pyramids appearing dark in color; thus their vascular status might well be analogous to that of the reflex kidney. Experimentally, irritation of the splanchnic nerves has been shown to cause oliguria and conversely section or anesthetic block will cause prolonged polyuria. Attempts as early as 1922 were made to combat therapeutically the renal vasoconstriction in reflex anuria. Neuwirt⁴ first successfully relieved such anuria by means of splanchnic block. Others repeated this observation. Some have advocated spinal anesthesia. Splanchnic block entails the application of a large quantity of anesthetic solution directly to the splanchnic plexus, which may more thoroughly interrupt the sympathetic flow. The duration of splanchnic block would seem longer than one would expect in spinal anesthesia. In transfusion anurias, splanchnic block is advisable but, as stated by Peters, it is "the key" which unlocks the door to further judicious therapy because the establishment of diuresis, while an essential step, far from insures recovery for the patient. Careful observation of the chemical balance of the patient may often clearly guide the treatment. The kidneys must have a continuously positive water balance. Hence, dehydration must be watched for, prevented, or treated. Saline is best to overcome dehydration for the sodium ion is necessary to fix the water to the tissues. However, because saline is taken up by the tissues, it may not be as good in certain stages of an oliguria as glucose solutions, for the water

²Peters, H. Raymond: *Ann. Int. Med.* 16: 547, 1942.

³Wiener, A. S.: *Blood Groups and Blood Transfusion*, ed. 3, Springfield, Ill., 1943. Charles C Thomas.

⁴Neuwirt, K.: *Ztschr. f. urol. Chir.* 2: 75, 1922.

of a glucose solution is more available for renal excretion. While it is not possible for all laboratories to have equipment to perform routine sodium determination, the sodium level can be roughly surmised from a comparison of the blood chloride level and the carbon dioxide combining power. If the carbon dioxide combining power is high and the blood chloride level is low, then the sodium level is probably near normal. There should be definite attempts made to guard against alkalosis. It must be remembered that, no matter how successfully splanchnic block may relieve renal vasoconstriction, in any given case one may still have kidneys in which widespread tubular epithelial degeneration has developed and the prognosis must be judged accordingly. In Peters' case, there was a hemolytic reaction with prolonged anuria following transfusion of blood of the homologous group. After failure of other measures for nine days, diuresis followed within a few hours after a splanchnic block, and there was ultimate complete recovery of the patient. It is obvious that this case offers evidence in favor of a vasoconstrictive renal element in transfusion anuria similar to that of the so-called "reflex anuria."

There has been a tendency among many writers to believe that in all cases of anuria following hemolytic reaction to blood transfusion, the kidneys present blocked vessels at autopsy. This is not necessarily true. It is probable that more causes are due to a mechanism similar to the reflex anuria than are due to actual mechanical blocking of small renal vessels.

In regard to nonspecific reactions, these are very severe but are rarely fatal. They have the following characteristics: thirty to sixty minutes after the injection, the patient has a severe shock which is followed by rise in temperature. Other patients may complain of chill, and the rise in temperature may be only slight. It was first thought that this was due to the use of citrate but experiences have shown that this occurs with saline solution as well as with citrate solution. Wiener's experience is that one per cent of transfusions is followed by symptoms of an allergic nature, usually a generalized urticaria, with eruptions at times associated with edema. This may be due first to the use of the blood from a donor who may have eaten some food to which the patient is sensitive. It may be due to the fact that some allergic reactions are based on individual differences in the serum proteins. Wiener believes, without full proof, that this may be due to factors such as isohemolysins as, for example, in repeated transfusions of blood even of a homologous group. Rapid injection of blood into the circulation causes a sudden increase in blood volume, which causes an additional load on the cardiovascular system. It causes a distention of the peripheral veins, coughing, fullness in the head, and vertigo. If these symptoms are not heeded and the transfusion is continued, the patient may go into collapse.

A problem which arises in blood transfusion work is how to distinguish the nonspecific chills following a transfusion from those chills which are based specifically on the incompatibility of the donor's blood. The first step is to repeat the grouping and cross-matching tests on samples of blood taken before the transfusion and also on fresh samples of blood to determine whether there has been an error in grouping. A sample taken from the patient after the transfusion should also be examined for hemoglobinemia and for icterus index, and, at the same time, the urine should be examined. Tests for M and N should be

made. If the M and N types of the patient and donor are different, tests on patient's blood with anti-M and anti-N sera will determine whether the donor's blood is still present in the circulation of the patient. If the bloods were incompatible, rapid elimination of donor's cells will have occurred. This test cannot be done if the M and N types are the same in both donor and recipient.

Differential Agglutination.⁵—

The principle of the differential agglutination test is to take a sample of the patient's blood after a transfusion with universal donor blood and test it with serum capable of agglutinating the patient's cells. Since the donor belongs to group O, his cells will not be agglutinated by the specific antiserum. For example, if an individual of group A is given group O blood, a count may be made of those cells not agglutinable by anti-A serum after the transfusion. Group O cells are not agglutinable by anti-A serum, but the patient's group A cells are, and thus it may be assumed that any inagglutinable cells found are the transfused cells. However, it must be remembered that in normal blood, approximately 50,000 cells per cu. mm. are not agglutinable by specific antisera, and this must be taken into account when the test is performed.

The method of tracing the fate of transfused red blood cells was first used by Todd and White⁶ in cattle. Ashby⁷ used the method for the first time in man for patients not belonging to group O and transfused with blood from universal donors.

When the patient receives blood of his own group, the differential agglutination test may be made only provided the M and N qualities of the donor and recipient differ. The results with anti-M serum are more striking than when group O blood is used for patients of groups A, B, and AB, for, if tests are made using anti-M serum on blood containing the M agglutinin, very few cells remain unagglutinated as contrasted with the 50,000 per cu. mm. not agglutinable by anti-A or anti-B sera. For example, if OMN blood is transfused to an ON patient, when tests are made using anti-M serum on the patient's blood after the transfusion, only the donor's MN cells are agglutinated; any unagglutinated cells are the patient's. If the donor is ON and the patient is OMN, the unagglutinated cells in tests with anti-M serum are the donor's.

Landsteiner, Levine, and Janes,⁸ Wiener,⁹ and Dekkers¹⁰ established that the blood cells of the donor survive in the patient's circulation for periods up to 3 to 4 months in the usual case where the patient is transfused with fresh compatible blood either from a universal donor or from a donor of the homologous group. Wiener and Schaefer¹¹ showed that the survival time of erythrocytes in bank blood is roughly in inverse proportion to the period of storage.

If incompatible blood is transfused, it remains in the circulation usually for only a short time,^{12, 13} so that even if the transfusion is tolerated, the trans-

fusion at best is of only transient benefit because of the rapid destruction of blood cells. However, Jervell¹⁴ found incompatible cells in an infant for more than six weeks after a transfusion, and Wiener found group AB cells present in a group O infant 50 days after a transfusion.

The method of making the test is to dilute the patient's blood, before the transfusion, with potent specific antiserum, in the usual manner for making a red blood count. Count the number of inagglutinable cells per cu. mm. in the patient's blood.

Repeat this test after the transfusion.

To determine the number of donor cells per cu. mm., subtract the number of inagglutinable cells before the transfusion from the number after the transfusion, and record the number per cu. mm.

If the count after the transfusion exceeds the count before the transfusion, it is assumed that the transfused erythrocytes are still present in the patient's blood.

Wiener and Peters¹⁵ applied this method of differential agglutination to the study of post-transfusion hemolytic reactions. They found that even when patient and donor are of the same blood group, if the bloods are incompatible due to factors other than **A** or **B**, the donor's cells are eliminated rapidly from the patient's circulation, within a period of a few hours or days, rather than in three or four months. The diagnosis of hemolytic transfusion reactions using this method rests on the assumption that donor's blood has been eliminated from the patient's circulation.

PREVENTION OF HEMOLYTIC REACTIONS

No matter how carefully one groups bloods and performs all the tests for compatibility, certain reactions seem bound to occur. This is possibly due to the fact that there are as yet certain facts about the problem of intragroup reactions which have not been solved. Accordingly, Wiener and associates¹⁶ suggested the use of a **biologic test** to supplement these in vitro tests commonly used. The use of a biologic test was suggested first by Oehlecker,¹⁷ who advised the injection of 10 c.c. of blood, waiting ten minutes, and then proceeding with the remainder of the blood if no reaction occurs. This method did not work out so well because the reaction is often delayed beyond the ten-minute period of Oehlecker. Wiener¹⁶ therefore recommended the following procedure:

Allow 50 c.c. of the donor's citrated blood to run in. After two hours have elapsed, if no reaction has occurred, administer the balance of 100 c.c. of blood. If a reaction occurs, withdraw 10 c.c. of blood from the patient and treat it in the same manner as the pretransfusion citrated sample used for the cross-matching test. Centrifuge the citrated blood samples and compare the color of the plasma in the two tubes. The syringe and needles **must be dry**.

If there is no change in the appearance of the patient's plasma, proceed with the transfusion of larger amounts of donor's blood. If the supernatant plasma of the post-transfusion specimen is distinctly redder than that of the pretransfusion sample, give no more of this donor's blood.

¹⁷Oehlecker, F.: *Die Bluttransfusion*, Vienna, 1933, Urban & Schwarzenberg.

After 100 c.c. of the donor's blood have been injected, it is possible to demonstrate the survival of the donor's cells by the method of differential agglutination (see page 1112) where the biologic test is negative, in patients having a red cell count of two and one-half million cells or less.

In positive reactions, two hours after the test injection of 50 c.c. of blood, patient may have a severe chill and rise in temperature, but clinical symptoms may be mild or absent. Place more reliance on the appearance of the patient's plasma which will show a distinct rise in icteric index as compared to the pretransfusion sample.

BLOOD PLASMA AS A SUBSTITUTE FOR WHOLE BLOOD IN TRANSFUSION

An enormous amount of literature has been accumulated regarding the use of blood plasma as a substitute for whole blood for transfusion in certain indicated cases. The advantages of plasma are that it can be used without typing, that it may be stored in liquid, frozen, or dried states for months or years and then administered safely without significant deterioration of its component qualities. It is readily available for immediate use and when injected does not increase the concentration of red blood cells in cases of shock and burns where hemoconcentration is already present. Manifestly, the use of whole blood where hemoconcentration is already present is contraindicated.

Historical Data Upon the Use of Liquid Plasma*

Blood plasma as a substitute for whole blood was suggested as early as March, 1918, by Gordon R. Ward¹ in England. He pointed out that one of the chief troubles with whole blood was that the recipient's plasma might hemolyze the corpuscles of the donor. He made the observation that death from hemorrhage was not due to lack of hemoglobin but from loss of fluid, and thus the great need in these patients is for the replacement of the depleted fluid. He suggested that this could be done by the administration of citrated plasma which could be preserved easily and injected safely.

Rous and Wilson² in 1918, while working on hemorrhage in animals, used plasma to replace the blood loss. As a result of their experiments they pointed out that the replacement of red blood cells is not essential because even in severe hemorrhage a sufficient number of cells remains to support life. The loss of blood volume is the important factor. Following gross hemorrhage they were able to restore the blood pressure to normal and maintain it by replacing the removed blood with an equal quantity of plasma. Where hemorrhage is too great, loss of red blood cells is important also.

Mann,³ in 1918, discussed the use of serum for treating surgical shock produced experimentally in dogs. He noted that the parenteral injection of homologous serum produced results which were as good as or even better than any of the methods employed in the treatment of experimental shock. It is

*Many of these historical facts were found in the publication by Lt. Comdr. L. R. Newhouser, U. S. Navy, and Captain D. B. Kendrick, Jr., U. S. Army, Medical Corps, entitled, "Human Plasma" prepared April, 1941.

worthy of mention that his best results were obtained with relatively large doses of serum. He asserted that homologous serum might be of value under conditions where serum could be kept and whole blood could not be obtained.

Strumia⁴ began using human serum intravenously in 1927 for the treatment of severe infections. Later in 1927 he began using plasma because of its simplicity of preparation and its greater yield. It was noted then that even heterologous plasma given intravenously caused no reactions whereas homologous sera commonly caused severe reactions. Gradwohl^{4a} recommended plasma in the treatment of a severe burn case. This difference in behavior of plasma and serum had previously been observed and commented on by Brodie⁵ in 1900. Untoward reactions from serum were thought by him to be due to the process of fibrin precipitation when serum is separated from the clotting blood. This hypothesis continues to be conjectural.

Weech, Goettsch, and Reeves⁶ in 1933 while doing plasmapheresis experiments in dogs were able to produce a normal state in their animals by administering transfusions of normal dog serum.

The use of plasma intravenously in man as a hemostatic agent was reported by Filatov and Kartasevskij⁷ in 1935. The same year Heinatz and Sokolow⁸ used plasma in the treatment of hemolytic shock.

Elliott⁹ in 1936 suggested the use of untyped serum and plasma for the treatment of surgical, obstetrical, or traumatic shock where transfusions were indicated. He rationalized that the need for replacing the lost blood volume was more important than the red blood cells, as the maintenance of osmotic pressure is a function of the plasma proteins. Elliott also propounded the idea that liquid plasma could be stored for long periods without deterioration. The findings of other investigators have supported his contentions.

Fantus¹⁰ in 1937, advocated the use of normal human serum because of its therapeutic and natural immunizing properties. He states that in shock without hemorrhage and in burns the intravenous injection of blood serum is much more rational than that of blood, because these patients usually have an excess of red blood cells per cubic millimeter.

Alovski and Burceva¹¹ published a favorable report in 1937 on the use of plasma as a substitute for whole blood in gynecologic conditions. Mahoney,¹² in 1938, recorded encouraging results with preserved plasma in the treatment of experimental and clinical shock. Elkinton¹³ and McClure,¹⁴ 1939, working separately, obtained good results with plasma in burn cases. Tatum, Elliott, and Nessel,¹⁵ 1939, suggested a technic for the preparation

of whole blood substitutes in war conditions. Plasma was recommended as "an ideal substitute for whole blood in the emergency treatment of shock and hemorrhage from war wounds." They outlined the technic of collecting blood in a vacuum bottle, centrifuging the blood, and then aspirating the supernatant plasma into a second vacuum bottle for storage. In 1940 Elliott, Busby, and Tatum¹⁶ recommended the use of dilute, preserved, liquid plasma. The same year Strumia⁴ advocated citrated blood plasma without cross-matching for the treatment of burns and shock. Thalhimer¹⁷ reported favorably on the use of convalescent serum for administering antibodies. Best and

Whitby,²¹ 1941, after using it for the treatment of shock and hemorrhage in air raid casualties in England, concluded that plasma and blood are equally effective in restoring blood volume in injuries of this type.

What Is Shock?—

An understanding of the physiology and mechanism of traumatic shock is necessary to comprehend the advantages of the use of blood plasma over whole blood. What is shock? Many theories have been advanced about shock. They are embodied under the twelve different theories in Table 120.

Three ways of classifying shock have been proposed. The first is determined by origin; i.e., traumatic, operative, burn, obstetric, medical shock, etc. The second classification, according to Harkins,* is faulty in the first instance in that the condition is primary but it is not shock; in the second instance, it is shock but it is not primary. Harkins recommends abandonment of the term primary shock. The third classification is that of Blalock, who divides shock into (1) the hematogenic type, usually called secondary, traumatic, and operative or surgical shock; (2) the neurogenic type, usually called primary shock, with a fall in blood pressure, of which shock due to spinal anesthesia or fainting is a type; (3) the vasogenic type, of which histamine shock is a type, the action being directly on the blood vessels; and (4) the cardiogenic type, in which the veins are distended. This condition is very rare.

The following definitions quoted from Harkins* indicate the multiplicity of opinions on what shock really is.

DEFINITIONS OF SHOCK

Travers (1826)	Shock is a species of functional concussion by which the influence of the brain over the organ of circulation is deranged or suspended.
Delcasse (1834)	An arrest of innervation without which all organs pass into insensibility. (An old way of expressing Meltzer's inhibition theory.)
Gross (1872)	A manifestation of a rude unhinging of the machinery of life.
Piéchaud (1880)	Le choc est un état général plus ou moins grave consécutif aux traumatismes, spécialement aux plaies par armes à feu et aux grands écrasements, caractérisé par l'affaiblissement des pulsations du coeur, l'abaissement de la tension, la pâleur des tissus, un certain degré d'anesthésie joint à la faiblesse musculaire, avec conservation de l'intelligence.
Mansell-Moullin (1882)	A sudden check to the circulation brought about through the agency of the nervous system.
Roger (1892)	Le choc est un état morbide qui peut se produire à la suite de fortes excitations du système nerveux et qui est caractérisé par un ensemble d'actes inhibitoires dont un seul, l'arrêt des échanges entre le sang et les tissus semble constant et indispensable.
Lockhart Mummery (1905)	Surgical shock is a condition produced by exhaustion of the vasomotor centers and the resulting great fall in blood pressure.
Lockhart Mummery (1910)	A condition of lowered blood pressure resulting from exhaustion of the vasomotor centers.
Gray and Parsons (1912)	The reaction of the central nervous system to exaggerated or abnormal afferent impulses.
Morison and Hooker (1915)	A low arterial blood pressure of such duration that recovery is impossible.

*Harkins, Henry N.: *Surgery* 9: 231, 447, 607, 1941.

²¹Kekwick, A., Marriott, H. L., Maycock, W. L. A., and Whitby, L. E. H.: *Lancet* 1: 99, 1941.

DEFINITIONS OF SHOCK (CONT'D)

Brown (1917)	Exhaustion of the food material—the Nissl granules—stored in the nerve cells, more particularly those of the vasomotor centers.
Quénu (1918)	Toxémie traumatique depressive.
Cannon (1919, 1923)	Exemia.
Meek (1926)	A decrease in the effective circulatory volume.
Schuberth (1936)	A peripheral circulatory insufficiency.
Davis (1937)	An anoxemia which is the resultant of such factors as oligemia, lowered blood pressure, diminished flow of blood, and peripheral vasoconstriction.
Tomb (1937)	The collapse of the circulation from overstimulation of the sympathetic nervous system.
Griswold (1938)	A deficiency in circulating blood volume.
Moon (1938)	A circulatory deficiency, neither cardiac nor vasomotor in origin, characterized by decreased blood volume, decreased cardiac output (reduced volume flow), and by increased concentration of the blood.
Devine (1939)	A state of depression of all the reflex arcs accompanied by circulatory depression.
Minot and Blalock (1940)	Peripheral circulatory failure resulting from a discrepancy in the size of the vascular bed and the volume of intravascular fluid.
Selye, Dosne, Bassett, and Whittaker (1940)	A condition of suddenly developing general damage.
Freeman (1940)	The clinical condition characterized by progressive loss of circulating blood volume, brought about by the tissue anoxia which results from inadequate circulation.

The conclusion of Harkins* as to the definition of shock, from the various opinions given in the literature, is that it is a progressive vasoconstrictive oligemic anoxia. A further descriptive definition by Harkins of shock is that it is an oligemia *initiated by* traumatic local fluid loss, either whole blood, plasma, or both; *accompanied by* decreased cardiac output, diminished volume flow, lowered venous pressure, decreased oxygen consumption, arteriolar vasoconstriction, acapnia, and secondary blood pressure fall; and *perpetuated by* a summation of these factors and possibly hyperpotassemia, increased generalized capillary permeability, anoxia, action of tissue metabolites, and deficiency of adrenal cortical hormone. Other changes, both chemical and pathologic, often occur in shock, including increased blood nonprotein nitrogen, decreased coagulability of the blood, and, in some instances, increase in plasma magnesium.

Moon²² states that *hemoconcentration is the earliest detectable sign of threatened circulatory deficiency of capillary origin and it is as ominous as a decline in blood pressure*. In shock, abnormal conditions exist which permit blood plasma to escape by leakage into the tissue spaces. It can be detected by increased volume of red cells shown by hematocrit, by an increased specific gravity of the whole blood, by an increased hemoglobin content, or increased red count. A definite increase in either of these indicates hemoconcentration but the degree and significance of it cannot be estimated except by comparison with previous data. The mechanism of hemoconcentration is based upon studies of Heidenhain made some fifty years ago. He showed that the maximum flow of lymph coincided with the period of minimum arterial blood pressure. He interpreted these results as demonstrating secretory activity

*Harkins, Henry N.: *Surgery* 9: 231, 447, 607, 1941.

²²Moon, V. H.: *Am. J. Clin. Path.* 11: 361, 1941; *Shock and Related Capillary Phenomena*, New York, 1938. Oxford University Press; *Ann. Int. Med.* 13: 451, 1939; *Arch. Path.* 20: 561, 1935.

of capillary endothelium. Recent investigations, however, show that the increased flow of lymph and the accompanying phenomena including hemoconcentration are due, not to increased secretory activity, but to endothelial damage. The injection of certain substances, such as watery extracts of various normal tissues, causes a disturbance of the systemic circulation, characterized by weakness, pallor, rapid pulse, perspiration, thirst, nausea, vomiting, rapid shallow respirations, loss of tissue turgor, restlessness or apathy, low temperature, and a declining blood pressure. These are the important features in the clinical syndrome of shock. They are quite similar to the effects of serious loss of blood by hemorrhage. In shock, there is a disparity between the volume of blood and the volume capacity of the vascular bed stream, due to two causes; first, a decrease in the blood volume; and, second, an increase in the volume capacity of the vascular bed. The total blood volume is lowered by leakage of plasma into tissue spaces, and the effective volume is reduced by sequestration of blood in atonic capillaries and venules. The dilatation of these has increased their volume capacity. Furthermore, circulatory failure of capillary origin is accompanied by a characteristic group of departures from physiologic constants. The total blood volume, the volume flow, the oxygen content, carbon dioxide combining power, chloride content, and coagulability of the blood are reduced. All metabolic activities are decreased. The red cell count, hemoglobin content, specific gravity, nonprotein nitrogen, sugar, and potassium content of the blood are increased. In addition, there are visceral alterations which are seen at autopsy, which are marked diffuse capillo-venous congestion in the lungs, mucosae, and in parenchymatous organs; edema of soft visceral tissues and effusions in serous cavities; petechial hemorrhages in the lungs, parenchymatous organs, and in mucous and serous surfaces. Kidneys show parenchymatous degeneration. Liver shows severe degeneration and central necrosis. The myocardium may or may not show microscopic evidence of degeneration. These are all due to lack of oxygen. Spleen is flabby and relatively bloodless, sometimes contracted, seldom congested.

In reference to burns, the contribution of Lee, Elkinton, and Wolff²³ on "The Management of Shock and Toxemia in Severe Burns" bears consideration. They showed that a chemical study of blood from patients with extensive superficial burns showed definite hypoproteinemia concomitant with hemoconcentration. Repeated transfusions of plasma controlled these conditions because the capillaries returned to a state of normal permeability about 48 hours after the burn. At this time, the plasma volume and circulating plasma protein are returned to normal by a large transfusion of plasma. Shock, which follows every severe burn, is the result of circulatory failure which begins within a few hours and persists for two or three days after the burn. It is caused by a shift of fluid, or leakage of plasma, into tissue spaces, resulting in hemoconcentration, circulatory failure, and massive edema at the burn site. In spite of this extreme hemoconcentration, the burned patient is not dehydrated but shows an abnormal distribution of fluid and a serious impairment of the mechanism which controls its distribution. This results in a

²³Lee, Walter E., Elkinton, J. Russell, and Wolff, William A.: *Pennsylvania M. J.* 44: 1114, 1941.

paradoxical situation of concentrated, partially dehydrated blood flowing through waterlogged tissues. This condition is aggravated by large amounts of oral or parenteral fluids without improving the circulation and may lead to water intoxication. Lee et al. showed in their series that plasma transfusions were used to marked advantage and were preferred to whole blood. Small plasma transfusions were given at the sixth, fifteenth, and thirtieth hours following the burn, thus preventing a dangerous drop in blood pressure and plasma volume. By the fortieth hour, the capillaries had recovered sufficiently to hold back protein, and a large transfusion of 900 c.c. was then given. They give the following working formula to determine the amount of plasma required by ordinary cases—enough plasma should be given to keep the hematocrit value between 50 and 55 per cent cells, and the plasma protein level about 6 grams per cent until the capillaries return to a normal state of permeability. At that time enough plasma is given to restore the plasma volume to normal.

The following formula is offered to meet this requirement: Plasma protein requirement in grams =

$$3.5 W - \frac{W (100 - H_o) H_n P_o}{2 (100 - H_n) H_o}$$

W = body weight in kilograms.

H_n = normal hematocrit value, per cent cells.

H_o = observed hematocrit.

P_o = observed plasma protein.

The plasma protein requirement in grams multiplied by 14 gives the volume of plasma required, expressed in c.c.

This circulatory disturbance, of which hemoconcentration is characteristic, develops in connection with extensive trauma or surgery, burns, poisoning with certain drugs and chemicals; severe metabolic intoxication, abdominal emergencies such as perforation, strangulation, pancreatitis, mesenteric thrombosis and others, and infections of unusual severity or virulence. In traumatic or surgical shock, therefore, there is seen hemoconcentration, and leakage of plasma into tissue spaces occurs. Blalock observed hemoconcentration in dogs when shock was induced by trauma, burns, or by intestinal manipulation.

Wound shock occurs two, three, or four hours after severe tissue injury, with pain and psychic factors through their effect upon the vascular system. Wound or secondary shock is characterized by a profound fall in blood pressure with a definite reduction in blood volume, even though no hemorrhage has occurred. Hemoconcentration is a characteristic of deranged physiology seen in shock, burns, infections, and use of chemicals. There is definite loss of fluid due to damaged endothelium.

The quickest method of determining the increased volume of red cells is the hematocrit technic (pages 594 ff.). Another step in estimation of hemoconcentration is a determination of the specific gravity of whole blood. This can be done by using the falling drop densitometer. (See pages 291 ff.) This procedure can be carried out in about two minutes. The average normal value of peripheral blood is a specific gravity of 1.0566 in the male and 1.0533 in the female. The protein content may be calculated from the plasma specific gravity. These tests are adapted to an estimation of fluid imbalance, which is the predominant characteristic of cases of shock. Simple dehydration represents acute water

loss, where there is a marked concentration of cells and dehydration is shown by the rise in cell volume and protein level. Treatment of this condition is simply by administration of fluids until values are reduced to approach the normal. In shock, however, there is a much more complicated mechanism. Here, an attempt must be made to overcome the severe arteriolar and venular spasm, the capillary paralysis and dilatation, and the great loss of circulating blood volume.

In hemorrhage, there is a fall in specific gravity of whole blood, a drop in the cell volume, and a slight drop in plasma specific gravity. Volume may be restored by transfusion of whole blood but this avails little in cases characterized by shock.

In burns, there is a loss of plasma and fluids by exudation, with shock due to anoxemia from changed permeability of capillaries, when toxic substances are absorbed from burned areas. Hemoconcentration and loss of plasma into the tissue spaces of the body occur in all these cases.

In nephritis, there is an indication for the use of fluids. Without edema but with marked albuminuria, whole blood may be used if there is considerable anemia present, and plasma is indicated only when blood is normal so far as anemia is concerned. Manifestly, plasma is indicated because the high protein loss is inadequate to maintain blood plasma proteins.

In nephritis with edema, plasma finds its greatest profit and usefulness. Lack of protein in the blood is due to loss of plasma through the kidneys. Reduced colloid pressure below the edema level permits increased osmotic pressure in the extravascular spaces and the accumulation of electrolytes and water in the tissues.

In nutritional edema, the edema is due to lack of blood protein because of an inadequate protein intake. Restoration of the blood plasma proteins to normal by transfusion of whole blood or plasma causes disappearance of the edema.

It is obvious that the use of plasma possesses definite advantages over whole blood in certain cases. The preparation of plasma can be carried out under bacteriologic precautions, and the product can be safely stored for months without deterioration. *Plasma requires no preliminary typing or cross-matching.* Liquid plasma may be prepared by laboratories and stored without refrigeration. It may be carried in the physician's emergency bag and given very quickly with a special apparatus to be described later.

The treatment of shock requires replacement of lost fluid and prevention of further fluid loss. According to Harkins,* the first aim can be best attained by adequate blood or plasma transfusion. The advantages in plasma transfusions consist of safety, simplicity, preservability, and portability. It must be remembered that in addition to the replacement of lost fluid, the prevention of further loss of fluid still remains a difficult part of the treatment, and for this part of the treatment, resort must be had to oxygen and adrenal cortical extract. As Harkins states, both are still in the experimental stage but offer considerable promise, in that oxygen may act in preventing anoxia, while adrenal cortical extract may prevent increased permeability of capillary wall and cell membranes and prevent a possible hyperpotassemia.

*Harkins, Henry N.: *Surgery* 9: 231, 447, 607, 1941.

The Technic of Preparation of Plasma

This technic requires the use of equipment by which blood may be obtained and the plasma prepared under sterile conditions. The equipment of choice is that manufactured by the Baxter Laboratories.

For the preparation of plasma by this method it is necessary to have a supply of Transfuso-Vacs of 500 c.c. size, containing 50 c.c. of 4% sodium citrate solution as anti-coagulant. The bottle is a sterile vacuum unit designed to fit centrifuge cups. For the removal of the supernatant plasma after centrifugation, sterile vacuum containers are available. These are known as "Plasma-Vacs," and are half full of physiologic saline or physiologic saline and dextrose for the preparation of dilute plasma, or are empty for the preparation of undiluted plasma. In addition, it is necessary to have a Plexitron expendable set or a Transfuso donor set, which consists of a special valve and needle for the control of the blood flow into the sterile vacuum container.

Prepare the blood donor in the usual manner. Cleanse the skin at the site of the needle insertion with alcohol-iodine. Constrict the upper arm with a short piece of rubber tubing or preferably with a blood pressure cuff.

Withdraw blood in the manner outlined on pages 1093 and 1094.

Before placing the blood in a refrigerator, break the remaining vacuum with a sterile air filter.

When the Transfuso-Vacs are to be centrifuged, remove the air filter and place the bottles in centrifuge cups and balance accurately. When centrifuging such large quantities, it is imperative that the bottles opposite one another be in perfect balance. If they are not, it is not possible to prepare clear plasma, and the centrifuge is likely to be damaged. For this balancing, place rubber bands around the neck of the lighter Transfuso-Vacs until they are in balance with the heavier ones.

Centrifuge for 45 minutes to 1 hour at 2,000 r.p.m. to separate the plasma from the cells. Any jarring of the centrifuge or the Transfuso-Vacs will disturb the cell layer, and poor plasma will result.

For removal of the supernatant plasma, substitute a long blunt-end needle for the donor needle on the Transfuso donor set. Clean thoroughly and autoclave this aspiration set before use. Observe the same rules and precautions with respect to closing the valve as given on page 1094. Plunge the donor valve needle through the rubber stopper of the Plasma-Vac. *Do not flame* the aspirating needle.

Cut away the thin rubber disk.

Disinfect the stopper of the Transfuso-Vac with alcohol-iodine, and insert an air filter.

Remove the long aspirating needle from its sterile wrappings and thrust it through the thin depression in the stopper into the plasma. It is important that the needle of the air filter be above the surface of the plasma. After inserting the long aspirating needle, open the valve gently without disturbing the bottle and allow the plasma to flow into the Plasma-Vac. See Fig. 272.

After all the plasma has been removed, close the valve, and allow the small amount of plasma remaining in the tubing to run into sterile test tubes by holding the tubing vertically and opening the valve slightly. Then test the plasma samples for sterility by anaerobic and aerobic cultures. If, after sufficient time has elapsed, the plasma is found to be sterile, it is ready for use or dilution. Do not use plasma containing undue amounts of fats or showing signs of high bilirubin content.

In the preparation of accessories all distilled water used should be pyrogen-free, sterile, and otherwise suitable.

The completed pooled plasma or serum in accordance with the regulations of the National Institutes of Health relating to plasma shall contain not more than 25 mg. of hemoglobin per 100 c.c.

What is meant by **pyrogen-free** distilled water? In 1911 Hort and Penfold¹ showed that the intravenous injection of freshly distilled water caused no symptoms in animals and in man, while the intravenous injection of the same water, after it had been incubated in unsterile vessels, caused a febrile reaction. These writers decided that this principle, provisionally called *pyrogen*, was a product associated with bacteria but was not a part of the bacterial bodies themselves. It is obvious that the fever-producing principle was still present after the water had been passed through a Berkefeld filter. These facts were confirmed by Siebert in 1923² by injecting distilled water intravenously into rabbits. In 1934 Banks³ reported that *Pseudomonas urea* and *scissa*, which he isolated from surface waters, were pyrogenic. Most of the work on pyrogenic substance has been confined to the bacteria found in waters. Co Tui and M. H. Schrift in an article, entitled "Production of Pyrogen by Some Bacteria,"⁴ showed that pyrogen production is much more widespread than was first embraced in the concepts of Siebert and Banks. They investigated eighteen strains of microorganisms of different genera, tribes, and families. They made their tests in three different ways: first, with bacterial strains grown in initially pyrogen-free broths; second, they used bacteria which were most convenient to grow on slants or in Kolle flasks, washing out the colonies with pyrogen-free physiologic saline solution containing 0.4 per cent phenol, inactivating for forty-five minutes by heat, then filtering and testing the sterile filtrate; third, they tested nine organisms in the form of vaccine made with pyrogen-free water. All the vaccines were passed through a Berkefeld filter.

Their estimate of a pyrogenic reaction in a dog was, first, a leukopenia thirty to forty-five minutes after the intravenous injection of the pyrogenic material; second, a rise of temperature thirty minutes after injection, reaching a peak in from two to four hours and returning to normal in four to five hours. In mildly severe reactions there were prostration and gastrointestinal symptoms, such as vomiting and diarrhea, both of which may contain blood. These symptoms are comparable to those in man.

The Pyrogenicity of Bacterial Contaminants Found in Biologic Products

The results of investigation by Probey and Pittman⁵ are pertinent. They investigated the pyrogenic properties of those microorganisms isolated from blood or plasma during the various stages of processing of dried normal human plasma, to determine the quantitative and qualitative nature of the thermal response of rabbits (a) to the living bacteria, (b) to heat-killed bacteria, and (c) to whole cultures grown in serum. We hope that this information will be useful as a guide in determining standards for biologics intended for human therapy.

The materials used were forty-nine cultures from eight processing laboratories widely distributed throughout the United States. Twenty-eight representative cultures were selected for study, including staphylococci, micrococci, streptococci, gram-negative bacilli, and sporeforming and nonsporeforming

gram-positive bacilli. The sodium chloride solution, which was used as the diluent, was prepared with one lot of sodium chloride proved by animal test to be pyrogen-free, and with water freshly redistilled in a glass still. Each lot was tested and accepted for use only if the rabbit thermal response induced was characteristic of pyrogen-free saline.

Methods.—The thermogenic properties of the test material were determined by the pyrogen test as described in the *U. S. Pharmacopoeia* XII, with a few changes.

The pyrexial response induced by the bacterial suspensions was computed by three procedures. The first procedure, *high above normal*, which is the U. S. P. method, bases the computation on the temperature deviation from the pretreatment normal temperature. The second method, *high above control*, records the difference between the maximum temperature deviation induced by the test material and that of the pyrogen-free control. The third procedure, *peak above control*, computes the pyrexia as the difference between the temperature induced by the test solution at the time of maximum temperature rise and the temperature of the pyrogen-free controls at the corresponding hour.

The pyrogen-free saline control in practically every instance, as originally reported by Hort and Penfold, induced a depression from the preinjection normal temperature. Therefore the normal physiologic reaction of the rabbit to injection of pyrogen-free saline is depression of the normal temperature. The fact that the pyrogen-free saline control induced a depression in the normal rabbit temperature caused these workers to believe that the evaluation of the pyrogen test should be predicated upon the normal physiologic response of the rabbit to injection with a pyrogen-free control and not upon the pretreatment normal temperature as is now recommended by the *U. S. Pharmacopoeia*. Another observation is that the quantitative characteristic of pyrogens, as reported for the bacteria studied, indicates that a slight febrile response in rabbits, of less than the 0.6° C. temperature elevation permitted by the *Pharmacopoeia* XII test, is in fact due to pyrogen contamination. This marginal amount of pyrogen may be sufficient to cause clinical reactions in humans, as Co Tui and Schrifft have observed that the rabbit is only one-third as sensitive to pyrogens as man. Co Tui² later recommended that the official test be more quantitative and suggested the use of several test doses to insure freedom from marginal pyrogen contamination. These writers believe that until the characteristics of pyrogens are more fully elucidated, it is indicated that the observation period of the animal thermal test should be continued until the maximum response has been reached or until the temperature curve has definitely entered the downward phase. Their work on contaminated blood or blood plasma during the processing of dried normal human plasma indicated that the contaminating bacteria were all capable of inducing fever in rabbits and that the count of bacteria in a contaminated blood product does not furnish an index of pyrogenicity.

The dog has a much more stable thermo-regulatory mechanism but is less sensitive to pyrogen than the rabbit. A positive test in the dog is so characteristic, however, with the additional symptoms of leukopenia, vomiting.

²Co Tui: *J. Am. Pharm. A. (Pract. Pharm. Ed.)* 5: 60-64, 1944.

and diarrhea, that it is unmistakable. For this reason, a positive test in the dog is much more significant than a negative one. To summarize, the rabbit is the better animal to test for the absence of pyrogen, while the dog is the better animal to establish the presence of pyrogen. Both animals must be used to complete the picture. Both dogs and rabbits have been used for several positive pyrogen tests without developing manifest immunity or tolerance.

The rabbit is approximately three times, and the dog at least six times, less sensitive than man to purified pyrogen from typhoid vaccine.

Test Dosages: Assuming that the above figures hold for pyrogen from other sources than the typhoid bacillus, the rabbit should receive as much as three times the maximum per kilo dose in man and the dog six times. In order to approximate the dose in man, the rabbit test dose must therefore be not less than 50 to 100 c.c. per kilo body weight. While this amount of fluid almost approximates the total blood volume of the animal, if the dose is injected in 10 to 30 minutes, the rabbit can easily take care of the plethora. But, in any event, the symptoms of plethora are different from those of a pyrogenic reaction. As the dog is to be used as a *positive* test animal, any dose which elicits the reaction shows the degree of pyrogenicity of the solution. This can be arrived at by trial and error, starting from a minimum dose of 250 c.c.

Procedure of the Test. The test is run in two parts, the preliminary part on rabbits, the confirmatory on dogs.

Preliminary Test.—Use albino rabbits of from 2½ to 3 kg. These rabbits should previously have been conditioned, for several days, to handling and taking of rectal temperatures until these procedures provoke no struggling and their rectal temperature readings are constant within 0.25° C. in three readings taken 15 minutes apart. Before injection, temperature readings taken at 15-minute intervals must not be over 39° C. The thermometers must be inserted the same distance beyond the internal sphincter of the rectum and allowed to remain there for two minutes.

The test solution is warmed to nearly the temperature of the animals; 50 c.c. per kilo body weight are injected into one animal, and 100 c.c. per kilo body weight into the second animal, no faster than 10 c.c. per minute. The temperature readings are taken every half hour for 4 hours after the injection. A rise of over 5° C. in 1 to 3 hours after injection is taken as presumptive evidence of the presence of pyrogen. A pyrogenic sample ought to give a more severe response with 100 c.c. than with 50 c.c.

Confirmatory Test: This is not necessary where a positive presumptive test is enough to lead to the condemnation of a product as unfit for human use. When more positive evidence may be required, in many legal or medicolegal complications, the clear-cut result of a positive dog test is not easy to controvert. Perform the test as follows: One healthy dog of 15 kg. body weight, conditioned to the taking of rectal temperature, with an initial rectal temperature of not over 39° C. and blood count not exceeding 20,000 white blood cells per cu. mm., is used. Depending upon the response of the rabbits, from 250 c.c. to 1,500 c.c. of the fluid are given intravenously through one of the external jugular veins, not faster than 30 c.c. per minute. The blood count is again taken 45 minutes and the temperature every half hour after the injection. The presence of leukopenia, a fall of 5,000 cells per cu. mm. or over, and temperature rise of 5° C. from 1 to 3 hours after the injection are evidences of the presence of pyrogen. The occurrence of emesis, prostration, and diarrhea are added checks.

Pyrogenic production is more common than is generally believed. It is not confined to any one group but occurs in a number of different groups of bacteria. Nor is it associated with nucleic acid, with pathogenicity, chromogenicity, nor with the property of taking the Gram stain. The production of pyrogen by a member of the yeast group suggests that even higher forms than bacteria may possess this property of pyrogen production. Chemically and immunologically pyrogen is still an unknown entity.

The importance of pyrogenic substances resides in the fact that they cause reactions in the use of improperly cleaned infusion equipment and intravenous solutions, such as Ringer's solution, glucose solution, citrated solutions of defibrinated blood, etc.

Dried Plasma*

In order to provide plasma in a compact form, resort has been made to the use of the lyophile technic, such as was worked out by Flosdorf and Mudd.¹ These two workers determined that the content of antibodies and complement of serum which is rapidly frozen and dehydrated from the frozen state under high vacuum suffer no detectable loss in the processing and, furthermore, that the rate of the subsequent deterioration is reduced to a small fraction of that which takes place in the liquid state. Scudder² stated that whole blood deteriorates rapidly, while lyophile plasma may show no appreciable change even after years. By the electrophoretic method of analysis the protein patterns for the lyophilized plasma differ little from that of the fresh control, while protein patterns dried at 37° C. show wide variation.

Method of Preparation of Dried Plasma.—

A number of methods have been described but the recommendation is made that if one desires to use dried plasma, it should be purchased from a reliable firm. 'Lyovac' is the brand of rapidly lyophilized normal human plasma prepared by Sharp & Dohme of Philadelphia. By permission of the copyright owner, Sharp & Dohme, Incorporated, as originally presented in their booklet (May, 1941) *'Lyovac' Normal Human Plasma*, the following facts and illustrations are reproduced. Blood by their process is obtained from healthy donors, who have undergone physical examinations and are found to be free of infectious disease and in good physical condition. History must be negative with respect to venereal disease and malaria. Blood is collected in bottles containing sodium citrate, using a closed system, under conditions approved by the National Institutes of Health, and a meticulous aseptic technic is rigidly exercised. Immediately after bleeding, the blood is centrifuged in the original containers, at a temperature of 2° to 4° C., for the purpose of separating the plasma from the cellular elements. Plasma from fifty bleedings is then pooled. The pooling of a large number of bleedings is carried out in order to obviate the necessity of classifying the plasma with respect to the blood group of the recipient before use. Typing is unnecessary because of two facts: first, the isoagglutinin titer of the pooled plasma is extremely low; and, second, no erythrocytes are present which might be agglutinated by the potentially incompatible serum of the recipient.

After pooling and after passing toxicity and sterility tests, 250 c.c. of plasma, representing approximately 500 c.c. of whole blood, are filled into individual containers. A sterile cotton-plugged rubber tube is then applied over the mouth of the container to maintain sterility until ready for the next

*Liquid plasma is preferred. Drying plasma preserves the hepatitis virus. Liquid plasma kept at room temperature for 6 months or longer loses its capacity to cause homologous serum jaundice.

¹Flosdorf, E. W., and Mudd, S.: *J. Immunol.* 29: 389, 1935.

²Scudder, J.: *Ann. Surg.* 112: 502, 1940.

step of the process. The container is of special design and made of a quality of glass which will withstand the rapid freezing and high vacuum to which it will be subjected.

The conversion of the liquid plasma to the frozen state is carried out at a temperature below the freezing point by immersing the container in a mixture consisting of dry ice in a suitable low-freezing solvent. By inclining the container away from the vertical position and rotating it, the material to be frozen forms a layer on the inside wall of the container; this procedure is referred to as "shelling." A large surface of the frozen material is thus exposed, which facilitates subsequent removal of water vapor when subjected to high vacuum.

Rapid freezing is highly important, for the lyophile technic aims at conversion of the substance with the least molecular rearrangement and at "fixing" of the original colloidal system.

The 'Vacule' ampul-vial, which contains the frozen plasma, is then subjected to a high vacuum in order to remove the water vapor without melting or softening the material itself. Advantage is taken at this step of the well-known physical fact that ice can be vaporized or sublimed under high vacuum without passing through the liquid phase. The necessary conditions for effecting this operation in practice are maintenance of a high vacuum by means of efficient vacuum pumps, and provision for removal of the water vapors thereby liberated.

The escaping water vapor may be removed by several methods, one of which is through the use of a condenser, the bulb being immersed in a freezing mixture so that the water is frozen therein as fast as the vacuum withdraws it from the material. The temperature of the material under process is gradually raised, after much of the moisture is removed, until it reaches approximately 20° C. or more. The dehydration is then continued until the residual moisture content is less than one per cent.

Tests have shown that the biologic activity and sterility of lyophile material are best preserved if they are maintained constantly under vacuum. For this reason the container is especially designed to maintain the desired vacuum after dehydration and is so constructed that into the neck of each container there is inserted a tightly fitting rubber stopper. This is done under vacuum after dehydration is completed. When the rubber stopper is in place, the vacuum employed in the dehydration process is released; the containers are removed from the lyophilizing apparatus and immediately flame-sealed. The vacuum, until the container is flame-sealed, is maintained by the rubber stopper in the constricted portion of the neck; the flame-sealing of the stem about one inch above the rubber stopper insures the maintenance of the existing vacuum indefinitely. The finished container, designated as a 'Vacule' flame-sealed ampul-vial, combines the best features of a glass flame-sealed ampul with those of a rubber-stoppered vial.

After a suitable interval, the finished 'Vacule' flame-sealed ampul-vials are tested to demonstrate the presence of adequate vacuum. Every container receives such inspection, and all containers which do not meet specifications are discarded. As with all biologicals, samples of the finished lyophilized blood

plasma are tested for sterility and safety. All the requirements and tests of the National Institutes of Health having been met, the product is then made available for use by the physician.

With each 'Vacule' ampul-vial of the lyophilized plasma a container of sterile distilled water is supplied. After breaking off the neck of the 'Vacule' ampul-vial at the mark just above the rubber stopper, the distilled water is transferred from the container by using the double-pointed needle which is supplied for this purpose. One end of the needle is inserted through the rubber stopper in the bottle of distilled water, which is then inverted, and the other end of the needle passed through the rubber stopper in the 'Vacule' ampul-vial of lyophilized plasma. Sufficient vacuum is present in the 'Vacule' ampul-vial to draw in all of the distilled water.

This finished lyophilized product is known as 'Lyovac' Normal Human Plasma. When desiccated it retains its therapeutic value and remains stable for at least five years and is available by the addition of pyrogen-free distilled water. It is stated that the content of specific and nonspecific antibodies, complement, and coagulating elements, together with three-fifths of the platelets, is essentially the same as that of the original fresh plasma.

Precautions Regarding the Use of This Product.—

Remove needle before all the water runs in.

Do not warm.

Dissolve in 5 minutes, shaking at room temperature, so as to obtain a clear solution.

Fig. 275.*

Fig. 276.

Directions for Administration of Normal Human Plasma

" 'Lyovac' Normal Human Plasma is packaged under high vacuum. Guard the container against breakage and loss of vacuum before restoration. Restore the plasma to liquid form as follows:

" Using the file provided with each package, file the neck of the 'Vacule' ampul-vial in the groove at the constriction in the neck (see Fig. 277).

" Holding the body of the 'Vacule' ampul-vial in one hand, and grasping the stem with the other hand, place the thumb directly opposite the file mark, exert outward pressure, and snap off the stem (see Fig. 278). The upper portion or 'skirt' of the rubber stopper is now

*Figs. 275 through 283 are published by permission of the copyright owner, Sharp & Dohme, Inc., as originally presented in their booklet (May, 1941) 'Lyovac' Normal Human Plasma.

Fig.
280.

Fig. 283.

exposed and generally will automatically snap down and back to a protective position over the edges of the neck of the 'Vacule' ampul-vial. If that does not occur immediately, a slight touch of the skirt of the rubber stopper will cause it to do so.

"Remove the shorter glass cap with its rubber washer and the stylet from the double-pointed needle. Insert this exposed end of the needle through the center of the stopper in the bottle of distilled water (see Fig. 279).

"Remove the glass cap from the other end of the double-pointed needle. Hold the 'Vacule' ampul-vial of plasma in one hand, invert the bottle of distilled water in the other hand, and push the exposed end of the needle through the depression in the stopper (see Fig. 280), making certain that the water is always above the ampul-vial of plasma (see Fig. 281). There is sufficient vacuum in the 'Vacule' ampul-vial to draw in all the distilled water.

"Withdraw the empty water bottle from the end of the needle, and in a few seconds, when the vacuum has been completely satisfied, remove the needle itself. Gentle agitation will help restoration to fluid state, which is usually complete within five minutes.

"Suspend the 'Vacule' ampul-vial of restored plasma by means of the tape provided (see Fig. 282).

"Remove sterile air filter assembly from its envelope and hang the air filter end on the suspending tape. Remove the glass cap from the needle and insert it diagonally through the rubber stopper in the 'Vacule' ampul-vial (see Fig. 283).

"Prepare sterile intravenous equipment by, first, unfolding the sterile muslin wrapping, then tighten the screw clamp and the metal collar of filter and flow control. Remove glass cap and stylet from the connecting needle and insert this needle through the rubber stopper of the 'Vacule' ampul-vial diagonally and in opposite direction to the air filter needle.

"Remove the rubber cap from the sterile glass needle adapter.

"Remove cotton plug from the glass tube containing the intravenous needle. Connect the glass needle adapter to the intravenous needle while it is still in the glass tube. Withdraw the intravenous needle from tube and seat it firmly on the adapter.

"Remove the glass cap from the intravenous needle. Displace the air in the entire intravenous equipment. To do this, hold the injecting needle end of the tubing above the level of the plasma in the 'Vacule' ampul-vial, and open the screw clamp. The plasma will then run in to fill the tubing and needle. Lower the needle end of the tubing until air bubbles are expelled. Then again hold the needle end above the level of the plasma until the flow control is filled up to the mark. Again lower the needle end of the tubing to expel the last few bubbles of air and fill the tubing and needle with plasma.

"Pinch the tubing between the fingers or tighten the clamp while the needle is being inserted into the vein. When satisfied that the needle is properly in the vein, slowly release the tubing or loosen the clamp and regulate the rate of flow by adjusting the clamp. The flow control, operating in conjunction with the clamp, provides complete control of the flow rate."

CLINICAL FACTS ON PLASMA ADMINISTRATION¹

Laboratory investigation, clinical study, and the experiences of World War II have proved beyond doubt the efficacy of human blood plasma as a substitute for whole blood in the management of secondary shock. The administration of plasma as a replacement therapy in shock is based upon the idea that the oligemia and pathophysiologic cycle of shock should be corrected with an agent that increases the total circulating volume and the total circulating osmotic pressure. Hence the essence of the treatment in shock is the *"immediate, rapid, adequate replacement of the depleted blood volume with the elements lost in the proportion that they have been or are being lost."*

The plasma used during a clinical investigation was prepared from whole blood by sedimentation or centrifugation in a closed vacuum bottle system (Baxter Plasma-Vac-Centri-Vac). After transfer to the storage bottle it was

¹The author is greatly indebted to Dr. J. J. Weinstein, Associate in Surgery, Gallinger Municipal Hospital and George Washington University Hospital, Washington, D. C., for permission to use this presentation (pp. 1130 to 1138).

kept at room temperature as unpooled, diluted, or undiluted plasma without chemical preservatives. Cultures of the plasma were made at regular intervals throughout the period of storage to insure sterility. Weinstein has kept plasma on a shelf in his laboratory for five years without serious gross or chemical changes; clinical use of this plasma has proved it to be effective.

The major changes in plasma stored at room temperature (25° C.) are: (1) the precipitation of fibrin and other protein-like substances; (2) a greenish discoloration, in daylight, due to storage of plasma; (3) a rapid decrease in the prothrombin; (4) a gradual decrease in complement specific antibodies and titers of isoagglutinins. The antihemophilic component of plasma and the globulin substance, or plasma thromboplastin of Howell, are well preserved. The total protein content likewise remains practically the same as the original figures when stored for as long as two years at 25° C.

Parenteral administration is accomplished by intravenous, intramuscular, and subcutaneous routes in both adults and infants. Table 121 from a previous report indicates the methods of administration and the average amounts of plasma per injection and per individual patient.

TABLE 121.—METHODS OF PLASMA ADMINISTRATION

METHOD OF ADMINISTRATION	NUMBER OF INJECTIONS	QUANTITY FOR EACH INJECTION	TOTAL AMOUNTS GIVEN TO INDIVIDUAL PATIENTS	RATE OF ABSORPTION
Intravenous	1500 adults	250-4000 c.c.	250-36,000 c.c.	immediate
	66 infants	50- 150 c.c.	50- 2,800 c.c.	immediate
Subcutaneous	200 adults	500-1000 c.c.	500-24,000 c.c.	3- 9 hours
	340 infants	30- 75 c.c.	30- 500 c.c.	3-18 hours
Intramuscular	15 adults	500-1000 c.c.	500- 4,000 c.c.	5- 9 hours

The reactions and complications encountered with plasma administration have been minimal. General reports reveal that the incidence varies between 0.5 per cent and 3 per cent. In a previous report of 1500 intravenous infusions of plasma, a 1 per cent reaction rate was observed, and in no case was there a severe or fatal reaction (J. J. W.). The following outline describes the types and number of reactions:

Reactions With Plasma

1500 Intravenous Infusions

Types of Reactions	Number of Reactions
<i>Possible Agglutinating:</i>	
pains in lumbar regions, dyspnea, headache, tachycardia, and drop in blood pressure	1
<i>Allergic:</i>	
urticaria, edema of face, and slight dyspnea	1
<i>Chills and Hyperpyrexia:</i>	
mild group	
chill of 15 to 30 minutes' duration	10
fever of 100 to 102° F.	
moderate group	
chill of 30 minutes to 1 hour	2
fever of 100 to 103° F.	
severe group	
chill of 1 hour or more	1
fever of 103 to 105° F.	

The one reaction which simulated a hemolytic one occurred in a male patient after the administration of 75 c.c. of undiluted plasma at a rapid rate (approximately 200 drops per minute). The plasma was group A and the recipient group B. The titer of the plasma was 1:80. This same plasma was administered to the patient later in the day, at 80 drops per minute, without any evidence of reaction or hemolysis of the recipient's cells.

As much as 4,000 c.c. of unpooled plasma of various types have been administered at a single continuous intravenous injection and as much as 36,000 c.c. have been administered to one patient over a period of time. It is wise, however, to give intravenously 10 c.c. of 10 per cent calcium gluconate after each 500 c.c. of plasma. This should not be given in the line of the administration set used for giving the plasma.

The clinical usage of liquid plasma has been varied. However, by far the most important use is as a substitute for whole blood in secondary shock due to whole blood loss or as the agent of choice in secondary shock due chiefly to the loss of plasma. The more common conditions for which plasma has been given by Dr. Jacob J. Weinstein are listed below:

1. Acute traumatic shock
2. Surgical shock
3. Acute hemorrhage with and without shock
4. Infectious shock
5. Intestinal obstruction with and without shock
6. Peritonitis
7. Pituitrin shock
8. Burns with and without shock
9. Preoperative support for an anticipated long and traumatizing operation
10. Preoperative and postoperative hypoproteinemia
11. Obstructive jaundice with hepatic insufficiency
12. Primary and secondary hepatic disease with hepatic insufficiency
13. Blood transfusion reaction with severe shock
14. Malnutrition, hypoproteinemia and avitaminosis
15. Cardiac edema associated with hypoproteinemia
16. Nephritis with nephrotic syndrome
17. Lipoid nephrosis
18. Diabetic coma with peripheral circulatory failure
19. Premature infants with dehydration and malnutrition
20. Nitrogen balance postoperatively.

The treatment of secondary shock resulting from the activities of everyday life is one of the important fields of therapy for the practicing physician and surgeon. Traumatic shock has increased during the past twenty-five years because of industrialization, faster travel by air, land, and sea, and modern warfare. Since many victims of accidents are in a state of shock from hemorrhage and trauma, heroic and immediate treatment is needed. Plasma offers an immediately available substitute for whole blood which will help correct the oligemia and interrupt the pathophysiologic cycle. The dosage and end results with plasma in the management of secondary shock are dependent upon the severity of the injury, the degree of blood loss, and the severity, degree, and duration of the shock.

No hard and fast rule can be made to govern the dosage of plasma for all cases. The variations are frequent and it is best to individualize each patient.

Experience has taught (J. J. W.) that the initial dose of plasma for various degrees of shock may be:

mild shock	-----	300 to 500 c.c.
moderate shock	-----	500 to 1000 c.c.
severe shock	-----	1000 to 1500 c.c.
profound shock	-----	1500 to 2000 c.c.

The average dose of plasma usually required to combat traumatic shock in patients admitted to the Gallinger Municipal Hospital is 1100 c.c. In a given case, however, it may be important that three, four, or even a larger number of liters be given. It is necessary to remember that large amounts are needed for the successful treatment of traumatic shock. A point for review is the custom

Fig. 284.—Case 1, Traumatic shock. (From White, Collins, and Weinstein: *Am. J. Surg.* 54: 701, 1941.)

of arbitrarily transfusing 250 to 500 c.c. of blood or plasma regardless of stature or the degree of shock. Did this develop because the usual amount of blood withdrawn from a donor is 500 c.c., or because the unit of plasma is 250 or 500 c.c.? Clinical experience and investigation show that this quantity has no significance. In giving plasma, it is better to err on the side of "too much too early" rather than "too little too late." However, Unger advises, particularly if the patient is bleeding externally or into a viscus, that 10 c.c. of 10 per cent calcium gluconate be given intravenously after each 1,000 c.c. of citrated blood. Otherwise the bleeding may become uncontrollable.

One of the best clinical criteria for adequate replacement therapy in secondary shock is the patient's response to the transfusion. A 15 to 25 mm. rise in systolic pressure can be expected with each pint of plasma in traumatic

shock if bleeding has stopped and no other factors are acting to produce further loss of plasma. Also if the initial dose is inadequate, give more, for no case should be regarded as irreversible until death is imminent.

Since overdosage is attended with little risk, and since inadequate amounts of plasma are wasted plasma therapy, one should always give large and repeated doses for the adequate management of shock. Fig. 284 exemplifies the importance of the immediate treatment of traumatic shock.

An interesting point for discussion in the management of shock is the rate of intravenous administration of plasma. The usual rate for the transfusion of blood is 8 to 10 c.c. per minute. The rate in shock is practically directly proportional to the degree of shock so that the greater the oligemia the greater the rate of transfusion. It is at times advisable to give 500 c.c. of plasma in 10 to 30 minutes. One of the simplest methods, in Weinstein's experience, for increasing the transfusion rate is to use a blood pressure bulb attached to the air vent of the transfusion bottle. With the screw closed, the injected air increases the pressure, thereby increasing the rate. A practical guide to the speed of injection is the clinical response of the patient. After the return of the systolic pressure to 100, the transfusion may be slowed to the conventional rate of 10 to 20 c.c. per minute until the maximal response is assured. Fig. 271 shows the Baxter pressure pump which enables administration of plasma at the normal rate or rapidly under pressure.

Surgical shock is the most common and one of the most important emergencies confronting active surgery. Results with plasma in surgical shock are not infrequently spectacular. One of the first effects of plasma upon a cold, clammy skin is the disappearance of the perspiration, and the return of warmth and color to the skin. The blood pressure response frequently follows this pattern. At first the systolic pressure rises. In fact, the systolic pressure rises more rapidly than the lagging diastolic pressure. As the pulse pressure begins to approach the normal, the diastolic pressure tends to rise more rapidly. After the functional level of 100 to 110 mm. of mercury is reached by the systolic pressure, the pulse rate may begin to decline. The pulse rate, however, is the last clinical sign to reflect the effect of treatment. It is not unusual for eight to twelve hours to pass before the pulse rate returns to normal after adequate plasma treatment of surgical shock.

Careful observations and recordings of the pulse rate in surgical patients frequently aid in the early diagnosis of secondary shock. An increase in pulse rate usually precedes the drop in blood pressure. The pulse pressure is likewise a good clinical guide to the results of therapy. The pulse pressure often directly reflects the intravascular volume. It is Weinstein's impression that the simplest and one of the most accurate guides to the detection and management of shock is the careful assessment of the pulse rate, the blood pressure, and the pulse pressure. Frequent determinations of the hematocrit, total protein, and peripheral blood counts also aid in the diagnosis and treatment of secondary shock. All patients who have been treated for surgical shock should be observed for long intervals so as to detect the development of recurrent secondary shock.

The prophylactic use of plasma in early stages of surgical shock often results in an excellent response and may allow the performance of more surgery

than would have been possible if the patient were allowed to go into a moderate or severe state of shock before treatment is instituted. See Fig. 285.

Internal or external hemorrhage, if severe enough, will cause shock and therefore requires the immediate replacement of part or all of the blood lost with carefully and accurately matched, sterile, nonsyphilitic, nonmalarial blood. It was this problem of having blood available at all times that led to the development of the donor system, then the blood bank, and finally blood plasma and serum. Two factors govern the development of hemorrhagic shock: (1)

SURGICAL SHOCK
GASTRIC RESECTION

Fig. 285.—Surgical shock. (Courtesy White, Collins, and Weinstein.)

amount and rate of blood loss or lost and the amount which continues to be lost; (2) the degree and power of the compensatory mechanism to compensate for the oligemia. True secondary shock develops from hemorrhage when the oligemia is present for a period long enough to produce peripheral stagnation and capillary permeability. It is the opinion of Brodin and Saint Gerons that the major danger of hemorrhage is the loss of blood volume and that the loss of red cells is secondary to this. An acute loss of 20 to 25 per cent of the total circulating blood volume will produce shock. The loss of 50 per cent of the red blood

cells, however, will not cause death or shock if the vascular volume is adequately maintained by plasma or serum. Experience has taught that plasma is an excellent substitute for whole blood in the management of hemorrhagic shock. Plasma is not the agent of choice for hemorrhagic shock—blood is. However, the early, adequate administration of plasma in hemorrhage will prevent the development of a critical oligemia and will frequently carry the patient over until compatible blood is available.

HEMORRHAGE WITH SHOCK

NORMAL DELIVERY - ATONIA OF UTERUS
WITH SEVERE ACUTE HEMORRHAGE

Fig. 286.—Hemorrhage with shock. (Courtesy White, Collins, and Weinstein.)

A point of caution is the confidence we may place in the effect of large doses of plasma in cases of massive hemorrhage with trauma, in those who must undergo surgery and further blood loss. These patients should be given blood and not plasma, for the continued loss of blood during surgery and the hypoxia produced by the anesthesia may produce unfavorable results. A simple rule for the administration of plasma and blood in the management of hemorrhage is to give one-half as much blood as plasma. Although plasma is not blood and one cannot expect the same results when transfusing plasma as are attained in whole blood transfusions, iso-osmotic plasma is the best blood substitute available today.

In extensive second and third degree burns there is a massive loss of plasma. The red blood cell count may rise to 8,000,000 or more, and the protein can fall as low as 3.2 gm. per 100 c.c. of plasma in the acute phase. Thirty to 60 per cent of the plasma volume is removed from the vascular bed in the acute phase of burns. Hence, the early and adequate use of large doses of plasma is important. The method of choice for determining the amount of plasma needed is the serial determinations of hematocrit, total protein, hemoglobin, red blood cell count, carbon-dioxide combining power, and urinary excretion and analysis. The blood findings closely parallel the degree of burn shock and the results of therapy.

Various rules have been promulgated for calculating the dose of plasma needed. For example, 100 c.c. of plasma should be given for every point the hematocrit level exceeds 45; or 50 c.c. of plasma for every point that the hemoglobin is above 100. To this figure is added 100 c.c. for each gram decrease below 6 of the total protein. Enough plasma is given to keep the total protein above 5.5 or 6 gm. per 100 c.c. of plasma. Close and persistent observation of the burned patient is vital, for the acute exudative phase persists for 24 to 48 or 72 hours. A shock state may appear again and again in this early phase of burns. If the burned patient is carried through the acute phase, the chances for recovery are greatly enhanced. The toxic stage, which is closely related to tissue protein metabolism, follows the acute exudative stage. During this period hypoproteinemia, edema, and water intoxication decrease the reparative powers. The hypoproteinemia is a result of increased catabolism as evidenced by the excessive nitrogen loss in the urine, the loss of serum from the granulating wounds, and the inadequate oral intake. Careful consideration should be given to the protein and fluid balance. Plasma will supply proteins for nitrogen utilization. In fact, if large enough doses of plasma are given daily, a burned patient can be kept in nitrogen balance. In passing, it may be said that the management of burns embodies the care of shock, toxemia, hypoproteinemia, water balance, and the local wounds.

Analysis of burns with shock treated at the Gallinger Municipal Hospital gives the following figures for average amounts of plasma required to overcome the acute shock stage successfully: 2400 c.c. of undiluted plasma for each adult in severe shock; 1800 c.c. in moderate shock.

The mortality for intestinal obstruction varies between 25 and 75 per cent, and the mortality for intestinal obstruction with resection of bowel is between 50 and 90 per cent. The patient with intestinal obstruction is usually much sicker than his clinical appearance. Most of the patients admitted to the Gallinger Municipal Hospital come in some time after their first symptoms of acute obstruction. The usual time is two to five days of illness. The mortality is in great part due to the pathologic changes. Patients with intestinal obstruction lose a great deal of fluid by vomiting, lose fluid and protein because of capillary permeability, are toxic from absorption of toxic waste products, and frequently are in or on the verge of secondary shock. These patients do not tolerate long surgical procedures, but frequently the disease process requires shocking and long operations. Plasma overcomes in great part the fluid imbalance present. It prevents or inhibits the development of shock. This is particularly true where long operations are carried out. Plasma has brought successful results in many cases, whereas the use of crystalloids only would have ended fatally. Blood studies

of cases with intestinal obstruction have shown findings characteristic of peripheral vascular failure. Frequently large and repeated doses of plasma are required to obtain a positive result. Occasionally one encounters a case of long-standing obstruction in which irreversible changes have occurred in the capillaries and vital centers, so that plasma will not overcome this state. These patients go on to exitus.

Surgical hypoproteinemia is a condition which is now being more carefully watched for and treated. The surgical patient who is to require intestinal surgery, particularly gastric resections, should be carefully prepared preoperatively as to the tissue and blood protein content. Frequently the patient with an ulcer of the stomach or a carcinoma of the stomach has gone through a long period of inadequate protein intake and is in a state of hypoproteinemia. This state will be exaggerated by the postoperative course, for very few of these patients take anything by mouth for the first four days postoperatively, and then the diet is limited for at least another week. The expression, "The operation was a success but the patient died," is often due to hypoproteinemia and the failure which goes with this state.

The hypoproteinemia that exists during nephrosis, chronic infections, low-grade peritonitis, specific and nonspecific colitis, and malnutrition responds frequently and satisfactorily to repeated plasma infusions. Plasma proteins are readily utilized by the body. This accessible and simple manner of supplying extra proteins to patients is of extreme importance. The edema associated with the critical low blood level of protein usually clears after sufficient infusion of plasma. This is particularly true in nephrosis and cardiac edema due to hypoproteinemia. The results with nephrosis are often only temporary and require repeated treatment with plasma. Hepatic insufficiency is another condition that is now being treated with plasma. White and Weinstein have seen spectacular results in patients with hepatorenal failure, particularly those following operative procedures for obstructive jaundice where the jaundice has caused actual liver damage.

It has been difficult to measure in figures their results with the treatment of hypoproteinemia, hepatorenal failure, etc., because the course is usually long and varied. However, one of the writers (J. J. W.) feels that clinically these patients are doing better than before the use of plasma.

One of the most enjoyable fields of investigation has been the use of plasma in the care of premature and newborn infants. The premature infant requires delicate care, adequate food and fluid, and very little handling. This is particularly true if a diarrhea develops, which is not infrequent. Blood transfusion is a common practice with infants, but that is a rather formidable procedure. However, few of these infants require red blood cells, and fresh plasma subcutaneously or intravenously will usually supply all that is needed. Also the simplicity and ease of administration offer a very important advantage as compared to the intravenous administration of blood. The complete picture of plasma administration in infants is unknown, but experience at the Gallinger Municipal Hospital has shown a decrease in morbidity and mortality with prospects for a greater future of plasma in the care of premature and newborn infants.

The **advantages of liquid plasma** are many and may be listed below.

1. Immediate availability.
2. Obviates typing, cross-matching.
3. Safe and relatively free from reaction.
4. Eliminates the waste of out-dated blood in a "blood bank."
5. The chances for transfer of syphilis are diminished. (Serologic tests are completed before storage and administration.)
6. Administered intravenously, intramuscularly, or subcutaneously.
7. May be used in large quantities and in repeated doses without pooling.
8. Stored for long periods (one and one-half years or more) at room temperature.
9. Easily transported.
10. May be quickly and simply prepared from citrated blood by centrifugation and aspiration.
11. Given without preliminary heating.
12. The small hospital can conveniently maintain a "Blood and Plasma Bank."
13. It will prevent many cases of surgical shock.
14. The more frequent use of plasma will aid any active surgical service in the preparation and care of patients.
15. Does not destroy normal plasma-cell ratio in secondary shock.

The **indications for the use of plasma**, whether dry or in liquid form, may be summarized as follows:

Use plasma in **secondary shock without hemorrhage**.

In **secondary shock with hemorrhage**, use plasma for the immediate emergency followed by whole blood as soon as possible, because there are hemoconcentration and loss of plasma from capillaries plus loss of red cells and plasma from the body. Shock develops earlier and is more severe if the loss of blood is great.

In **hemorrhage**, with loss of both cells and plasma from the body, use whole blood or plasma until whole blood can be obtained.

In **burns**, where there is loss of plasma and fluids by exudation, with shock due to anoxia from changed permeability of capillaries when toxic substances are absorbed from burned areas, use plasma. Whole blood is not indicated. In these cases, hemoconcentration and loss of plasma into the tissue spaces of the body occur.

In **infection**, with loss of blood protein, through the kidneys, use whole blood if the hemoglobin is below normal; plasma if it is normal.

In **nephritis**—without edema but with marked albuminuria—when high protein diet is inadequate to maintain blood plasma proteins, use whole blood if there is anemia present and plasma when blood count is normal.

In **nephritis**—with edema—use plasma to replace that lost through the kidney.

In **anemia**, use whole blood.

In **blood dyscrasias**, transfusion is a palliative measure and whole blood is most satisfactory.

In **nutritional edema**, with edema due to hypoproteinemia because of an inadequate intake of protein, use whole blood or plasma.

In **immunotransfusions**, when there are large quantities of specific antibodies present in convalescent blood, which are indicated in the treatment of certain infections, use whole blood or plasma.

Recommendations for Emergencies During War:

1. Every adult individual should be grouped and his group recorded. Personnel of military establishments should have records made and should have their group letters placed upon their identification tags.

2. Civilian populations in large centers should be organized into voluntary blood transfusion services.

3. Large quantities of blood should be received into the regulation vacuum bottles and refrigerated continuously, constituting a veritable wholesale blood bank.

4. As soon as the period of time has elapsed making the use of such whole blood unsafe, blood plasma should be withdrawn from these bottles, by the method already cited, and stored in sterile vacuum bottles.

5. A central agency* might assume control of this countrywide organization with the large branches constantly supplying them with information as to the number of liters of whole blood and blood plasma on hand and ready for use.

6. In times of emergency, this central organization could forward to any concentration point any quantity of whole blood or blood plasma desired.

Summary on Usage of Blood and Plasma

The transfusion of whole blood is still an essential procedure in acute hemorrhage and in some of the blood dyscrasias. It is of interest that there has been made available by a number of biological houses a modification of the original vacuum container for transfusion purposes. This container enables the storage of whole blood until the expiration time as a blood bank unit. The plasma prepared by sedimentation may be removed by the technic previously described or the bottle may be placed in a centrifuge cup and the plasma prepared by centrifugalization, resulting in a greater yield of clearer plasma.

Regarding the question of what form of plasma is preferable, it seems undeniable that for the optimum preservation of prothrombin, fluid plasma should be maintained in the frozen state. As stated by Strumia and McGraw,¹ plasma dried from the frozen state and restored with sterile pyrogen-free distilled water or plasma stored at room temperature (about 25° C.) for even short periods shows almost complete loss of prothrombin. It has been suggested² that prothrombin may be lost in the process of drying owing to the removal of carbon dioxide with resultant increased alkalinity. Plasma preserved in the liquid form at 4° C. maintains a fair quantity of prothrombin and complement, for a period of approximately fifty days, but causes maximal

*The use of plasma prepared by the American Red Cross was one of the greatest achievements of World War II, which is now happily over. So much plasma was prepared that a vast quantity was left over after the war. This excess has been distributed to hospitals free of charge throughout the United States. This war measure now has become a notable peace measure as well.

¹Strumia, Max M., and McGraw, John J.: *J. A. M. A.* 118: 427, 1942.

²Flosdorf, E. W., and Mudd, Stuart: *J. Immunol.* 29: 389, 1935.

flocculation within a few hours. Filtration is essential and the danger of bacterial growth from a chance contamination is not eliminated. While dried plasma prevents bacterial growth and flocculation, this material, when regenerated, has lost almost all the prothrombin and a portion of the complement. It has the advantage that it permits concentration if desired, but it is of little value for hypoprothrombinemia. Noteworthy is the advantage of the frozen plasma in that it prevents bacterial growth and flocculation and at the same time insures almost complete preservation of all specific elements, including prothrombin and complement. If properly thawed, it does not have to be filtered and the therapeutic value is practically equal to that of freshly prepared plasma. Thawing must be rapid in the water bath at 37° C., and thereafter, until administered, the liquid plasma must be kept at room temperature. It is the opinion of Strumia and McGraw that plasma maintained in the frozen state and properly thawed is almost identical to the original material.

Whole blood is best for pure blood loss. Plasma is better for shock, burns, and hypoproteinemias. Liquid plasma, when fresh, is best of all. When it must be stored, it is best stored in a frozen state because it retains its prothrombin and complement intact. Possibly the use of dried plasma is the most practicable of all forms of plasma preparation for large-scale operation.

AGGLUTINOGENS M AND N

Landsteiner and Levine¹ showed that when certain immune sera from rabbits which had been injected with human blood were absorbed with certain samples of human blood, they still contained agglutinins acting on the majority of bloods of all four groups, while other bloods were not agglutinated. Two of the factors demonstrable by these sera were designated M and N. These writers found that according to the content of agglutinogens M and N in blood cells, three distinct types of human blood could be distinguished: type M, which contains agglutinin M but lacks agglutinin N; type N, which contains agglutinin N but lacks M; and type MN, which contains both agglutinogens, M and N.

The distribution of these types is the same in each of the four blood groups, so that the agglutinogens M and N are unrelated to the agglutinogens A and B. Of 1,256 blood specimens, we* found 270, or 21.5 per cent, type M, 222, or 17.7 per cent, type N, and 764, or 60.8 per cent, type MN patients.

It is interesting to note that no agglutinins for N have been shown in human sera, and in only seven cases have agglutinins for M been found.² The testing sera for differentiating agglutinogens cannot be obtained as A and B antisera are, by venous puncture from human sources, but must be prepared artificially by immunizing rabbits. In order to produce anti-M serum, one must inject blood of type M (from group OM) into rabbits; one must inject blood of type N (group ON) into rabbits to produce anti-N serum.

Method of Producing Anti-M and Anti-N Sera†

First, find OM and ON subjects to furnish blood for the immunization of rabbits. Observe all sterile precautions throughout the entire procedure.

²Unger, Wiener, and Sonn: Am. J. Clin. Path. 16: 1, 1946.

Withdraw 50 c.c. of blood OM and 50 c.c. of blood ON directly into their respective 50 c.c. Rockefeller centrifuge tubes, each containing 4 c.c. of 3.8% sodium citrate solution. Shake to prevent clotting.

Wash with sterile saline (see page 2043) several times until all plasma has been removed. This prevents possible anaphylaxis and production of antibodies for human serum globulin. Restore to original volume. (Twelve c.c. of this blood added to 48 c.c. of saline furnishes sufficient material to inject four rabbits six times each.) It is well to pool several OM bloods for injecting the M rabbits and several ON bloods for injecting the N rabbits.

Use four rabbits* for the production of anti-M serum, and four* to produce anti-N serum. Each rabbit must be identified by an ear tag, and complete records kept. Inject into the marginal ear vein of each rabbit 2 c.c. of blood, using four of the rabbits for injection with M cells and four for injection with N cells. Repeat the injections daily for six days.

Allow one week's rest interval. Repeat the six injections, giving the first intramuscularly and the other five intravenously. Giving the first injection intramuscularly prevents anaphylaxis and possible agglutination of the cells and death of the rabbit.

Allow another rest interval of one week. Repeat the six injections, giving the first intramuscularly and the other five intravenously.

Wait another week and test to determine whether or not anti-M or anti-N agglutinins have been produced in any of the animals. The entire period of injections and intervals covers six weeks.

It will be found that not all rabbits will react well and produce an efficient agglutinating serum. Sometimes only one rabbit out of the four will develop agglutinins. For this reason it is necessary to test the serum of each rabbit for agglutinating substances before exsanguinating the rabbit from the carotid artery.

Preliminary Tests of M and N Antibodies.—Withdraw 2 c.c. blood from the ear vein of each rabbit, place in a clean, dry, sterile Kahn tube, properly labeled with the type letter and the number of the rabbit. Allow to clot. Loosen the clot, centrifuge, withdraw the supernatant serum, and place it in a clean, dry, sterile Kahn tube properly labeled. Inactivate at 56° C. for thirty minutes to prevent subsequent hemolysis and to inhibit the growth of any contaminating bacteria.

Since the sera of immunized rabbits contain species agglutinins, it is necessary to remove these before any tests can be performed. These are removed by absorption. To absorb anti-M serum, N¹ cells are added to the rabbit serum; to absorb anti-N serum, M² cells are used. Since the M serum is not easily overabsorbed while the N serum may be overabsorbed, greater care must be used in absorbing anti-N sera than is the case with anti-M sera. Absorptions are usually carried out at room temperature, using sufficient quantities of absorbing blood to insure complete removal of the species antibodies. If the absorptions are carried out at lower temperatures, smaller amounts of blood are required. Caution must be exercised in the preparation of the anti-N fluid so as to avoid overabsorption with M absorbing blood.

Dilute the serum 1:20 by adding two drops of serum to thirty-eight drops of saline. This gives 2 c.c. of fluid, representing a dilution of 1:20.

Place 1 c.c. in a Kahn tube.

Add 0.5 c.c. of washed cells to the serum. If preparing an anti-M serum, add 0.5 c.c. N cells, mix thoroughly, allow to stand one-half hour at room temperature, centrifuge, and use

*Four or more rabbits are used because many rabbits do not develop the antibody. Usually out of four rabbits perhaps only one will develop an anti-M or anti-N antibody sufficiently active to be useful in tests.

¹Pooled groups ON, AN, and BN cells.

²Pooled groups OM, AM, and BM cells.

the supernatant fluid. If preparing *anti-N serum*, use M cells, placing the tube in a glass of warm water in the incubator at 37° C. for thirty minutes, centrifuge, and use the supernatant fluid.

Test each serum against several specimens of M, N, and MN bloods. On a slide containing three wax rings, properly labeled, place one drop of M cells in the first ring, one drop of N cells in the second ring, and one drop of MN cells in the third ring. Add to each one drop of anti-M testing fluid. Rotate and examine periodically under the low power of the microscope for seven to ten minutes. Prepare a similar slide but use anti-N testing fluid instead of the anti-M. The sera show proper reaction provided (1) the anti-M serum agglutinates all M and MN cells within one or two minutes, but fails to agglutinate N cells after ten minutes; and (2) the anti-N serum agglutinates all N and MN cells in one or two minutes, but fails to agglutinate M cells within ten minutes. If the M fluid agglutinates N cells, or if the N serum agglutinates M cells, the serum must be re-absorbed, care being exercised not to overabsorb. If the anti-M serum fails to agglutinate M cells, or if the anti-N serum fails to agglutinate N cells, then the serum cannot be used.

Titrate the fluid, using the technic on page 1015. The M fluid should have a titer of at least 1:20. The N fluid need not be of a titer higher than from 1:8 to 1:16.

Collection of Anti-M or Anti-N Testing Fluids.—Having selected the rabbits which show agglutinin anti-M in a titer of at least 1:20, and the anti-N in a titer of at least 1:8 or 1:16, exsanguinate them by severing the carotid artery, using utmost sterile precautions, and obtaining the entire content of blood from each animal. For the method of bleeding rabbits from the carotid artery, see page 2040.

Collect the blood in clean, dry, sterile 50 c.c. Rockefeller centrifuge tubes, properly labeled. Cork immediately and allow to clot in a slanting position. Strike the tubes against the palm of the hand to loosen the clot. Refrigerate for twenty-four hours. Centrifuge at high speed for 15 to 30 minutes to separate the serum from the clot. Withdraw the serum, under sterile conditions, placing it in sterile 20 c.c. test tubes, properly labeled, and stoppered with cotton, and inactivate at 56° C. for 30 minutes. Save a few c.c. for absorption. Make ampules of the remaining serum, labeling with the rabbit's number, the type letter, date, and the notation "inactivated, unabsorbed." The serum will remain in good condition for a longer period if it is unabsorbed. Absorb only enough for several months' use.

Preparation of Testing Fluids Anti-M and Anti-N.—The species agglutinins from these two collections of blood from M and N rabbits must be treated as in the preliminary experimental work detailed above to remove species agglutinins. Under strict sterile conditions, dilute each serum to 15 to 25 times its volume with sterile physiologic saline and mix with the appropriate blood cells in order to complete absorption.

Absorption of M Serum.—Use all sterile precautions. Dilute this serum 1:20 with sterile saline. Divide it into two parts, each tube containing 10 c.c. It is better to handle small quantities of serum at a time. Place 5 c.c. of pooled, washed, packed N¹ cells in each M diluted serum. Cork each tube of serum, and mix by inverting back and forth about six times. Allow to stand 30 minutes. Centrifuge and test for the presence of anti-M and N agglutinins. This absorption is carried out at room temperature. Absorption is complete in the case of anti-M fluids when there is no longer a reaction with N bloods, but the anti-M serum must still agglutinate M and MN cells within a two-minute period.

Absorption of Anti-N Serum.—In the preparation of N fluids, great care must be exercised to prevent overabsorption. The preparation of N fluids is carried out slowly so that one may approach the end point of complete absorption very accurately. Place the anti-N tube, in which the anti-N serum has been in contact with the M² cells, in a glass of warm water (37° C.) in the incubator and allow it to stand the same length of time as in the case of the M fluid, namely, 30 minutes. Remove from the incubator and test. If it is not completely absorbed, add more cells, using only half the above quantity of M cells, and repeat the same technic in the incubator. This serum must agglutinate N and MN cells within two minutes but must not agglutinate M cells within a five- to ten-minute period.

Assuming that the M cells are no longer agglutinated by the anti-N serum, and the N cells are no longer agglutinated by the anti-M serum, the two products may be bottled. A small

¹Pooled groups ON, AN, and BN cells.

²Pooled groups OM, AM, and BM cells.

amount of Merthiolate, one part of a 1% solution to 100 parts of testing fluid, are added, giving a 1:10,000 concentration of Merthiolate.

Preservation of Anti-M and Anti-N Agglutinins With Toluol.—Levine¹ recommended toluol to preserve anti-M and anti-N agglutinins in testing fluids. One drop of toluol is added to each cubic centimeter of diagnostic fluid; this is then stoppered and sealed with paraffin. After thirty-two months, he found the anti-M just as active as the fluid freshly prepared from the same serum. Anti-N gave reactions which were only slightly less intense than those with the freshly prepared fluid. The best way to preserve antisera, however, is in the frozen state without the addition of any chemical.

Method of Using Anti-M and Anti-N Testing Fluids.—The preferred method is the centrifuge method. By mixing a small amount of cells with a drop of serum and centrifuging, the centrifuged cells at the bottom of the tube will not disperse when shaken if they contain the specific agglutinin. The mass of cells remains as a single large clump. If they break up into a homogeneous suspension, as seen under the microscope, the reaction is negative. The slide method may be used but for exact work the centrifuge method is preferred.

Technic of Open Slide Method of Testing for M and N Agglutinogens

Controls.—Have on hand suspensions of known type M, N, and MN cells. Use two slides with three wax rings each, properly labeled. Place one drop of M cell suspension in the rings labeled “M,” one drop of N cells in the “N” rings, and one drop of MN cells in the “MN” rings on each side. On the first slide, labeled “anti-M” serum add 1 drop of anti-M testing fluid to each ring. Add 1 drop of anti-N testing fluid to each ring on the second slide labeled “anti-N” testing fluid. Rotate and examine every 30 seconds under the low magnification of the microscope, recording a positive reaction when it occurs, and waiting at least five to ten minutes before recording a negative reaction. A positive reaction is agglutination of the erythrocytes; a negative reaction is lack of agglutination.

The M serum should agglutinate M and MN cells, but not N cells, while the N serum should agglutinate N and MN cells, but not M cells. If the controls indicate that the sera are in good condition, tests may be made on unknown bloods.

Technic of Testing Unknown Blood.—Place one drop of unknown cell suspension in each of two wax rings on a glass slide. The left-hand ring should be marked “M” and the right-hand ring “N.” Add 1 drop of anti-M testing fluid to the left ring and one drop of anti-N testing fluid to the right ring. Rotate and examine under the microscope periodically, recording agglutination when it occurs, but waiting at least five to ten minutes (as determined by the controls) before recording lack of agglutination. (Cell suspensions are described on pages 1005 and 1006.)

UNKNOWN CELLS + ANTI-M SERUM	UNKNOWN CELLS + ANTI-N SERUM	TYPE OF UNKNOWN
+	+	MN
+	-	M
-	+	N

+ = agglutination
- = no agglutination

Read the reactions as follows: If both sides show agglutination, unknown is MN. If the anti-M serum agglutinates the cells, but the anti-N serum does not, the unknown is type M. If the anti-N serum agglutinates the cells, while the anti-M serum does not, the type of the unknown is N.

If neither side shows agglutination, the sera must be discarded and new sera obtained.

¹Levine, Phillip: J. Lab. & Clin. Med. 26: 866, 1941.

In working with M and N testing fluids, as shown by Landsteiner and Levine, bloods containing factor **N** alone are more strongly agglutinated by anti-**N** testing fluids than bloods containing **M** and **N** together. Type N blood is twice as sensitive as type MN blood to agglutination with anti-**N** serum.* It must be emphasized that control bloods of all three types are necessary in the performance of M and N tests. Wiener has emphasized that in a large experience, using three different anti-**M** fluids and three different anti-**N** fluids, he has never found a discrepancy among the reactions. There are certain sources of error, however, which Wiener has outlined, which must be taken into account. First, great care must be used in the preparation of anti-**M** and anti-**N** testing fluids. *Overabsorption* is the fault of most beginners in making these fluids. He has shown that there may be interfering reactions caused by specific agglutinins other than those directed against M and N. Similar interfering reactions may be caused by natural or immune agglutinins against A and B, and there may be a coexistence in the same serum of more than one of the agglutinins against M and N. To obviate these difficulties, the preparation of the testing fluid by absorption should be carried out in the case of anti-**N** fluid by using a mixture of bloods of types OM, AM, and BM. Again, Wiener has shown that there is danger of false positive reactions from *underabsorption* of the immune sera. This particularly applies to the tests for N but may be prevented easily by the inclusion of negative control bloods. Errors are more likely to occur in using the slide method than the centrifuge test-tube method.

BLOOD GROUPS AND HEREDITY

For the practical application of blood transfusion, heredity is of importance because with a knowledge of the formulas of heredity we can understand that relatives are suitable for blood transfusions only when they possess compatible blood groups.

The serologic differences in the blood cells have been proved to be determined by heredity and are not influenced by environment. Ottenberg and Epstein¹ and von Dungern and Hirszfeld² proved that the four Landsteiner blood groups are inherited. Bernstein³ in 1925 proved the exact mechanism of heredity. These inherited factors follow Mendel's laws. With respect to what we mean by "Mendelian dominants," one must turn to the painstaking research of Johann Mendel, born in 1822, of German parentage, in the village of Heinzendorf, in Silesia. At the age of 21, in 1843, he entered the Augustinian Monastery at Brunn, Austria, there spending the remainder of his life except for a short period of study at Vienna. His name upon entrance to the Monastery became Gregor, and now he is known as Gregor Johann Mendel. In a little strip of garden behind the monastery building, Mendel conducted his experiments upon hybridization. In his rooms he hybridized mice, along the edge of the garden he experimented with bees, and in the garden itself, he crossed many kinds of plants. His famous experimental work was per-

*Wiener, Zinsher, and Selkove, J. Immunol. 27: 431, 1934.

¹Trans. New York Path. Soc. 8: 187, 1908.

²Ztschr. f. Immunitäts 6: 284, 1910.

³Ztschr. f. indukt. Abstammungs. u. Vererbungs 37: 237, 1925.

formed with garden peas, columbine, snapdragons, slipperworts, pumpkins, four-o'clocks, beans, etc. His work with garden peas is the most notable. Seven pairs of peas with contrasting characteristics were used by him, including smooth seeds and wrinkled seeds, yellow cotyledons and green cotyledons, inflated pods and constricted pods, yellow pods when unripe and green pods when unripe, flowers in the axils of the leaves and flowers at the ends of the stems, white seed coats and brown seed coats, tall plants and dwarf plants.

Mendel crossed tall plants with dwarf plants and produced the first filial generation, known as F_1 , all of which were tall. When these tall plants were selfed, they produced both tall and dwarf plants, there being three times as many tall plants as dwarf plants. In the second generation, two-thirds of the tall plants when selfed produced tall and dwarf plants in the ratio of 3:1, just like the F_1 plants. All the F_1 plants were tall, because, according to Mendel, the factor determining tallness was *dominant* to the factor for dwarfness. When hybrid tall plants were selfed, tallness showed up in the proportion of 3:1. In general, he found a factor which he called a *dominant* factor. This showed up always in the proportion of 3:1, while the factor which did not produce its effect in the presence of the contrasting factor he called *recessive*. Thus, *tallness* was the dominant factor and *dwarfness* was the recessive.

Mendel's work was published in 1866, but very little attention was paid to it until the botanists deVries, Correns, and von Tschermak reached conclusions similar to his, but independent of each other. His paper was then rediscovered and credit given to him after thirty years. Thus, in 1900, his work was made known to the scientific world.

The explanation of the heredity of blood groups may be found by studying the chromosomes of cells. There are 48 chromosomes in the human cell, or 24 pairs; in each cell of a mosquito there are 6 chromosomes, or 3 pairs; in each cell of a corn plant there are 20 chromosomes, or 10 pairs; in each cell of a certain species of crayfish, 200 chromosomes, or 100 pairs, etc. Within the chromosome, there are factors known as *genes* which are transmitted in a hereditary sense. Two such factors forming a contrasting part are said to be *alleles*, with an adjective formed from this word, *allelic*. Classifications based upon genetic formulas are known as *genotypes* and the final hereditary result is the *phenotype*. Thus in group A, we would call AA the genotype and A the phenotype; in group B, BB the genotype and B the phenotype; in group O, OO the genotype and O the phenotype, etc.

A germ cell (sperm or ovum) is called a *gamete* and the union of two gametes is called a *zygote*. A zygote is said to be a *homozygote* if the two members of the pair of factors are alike, and a *heterozygote* if the two members are different. Thus, AA is a homozygote and AO , a heterozygote. In the blood groups, A and B may be assumed to be pure strains from a genetic standpoint; that is, the genotype may be AA and BB . If it is as follows, AO or BO , A is dominant and O is recessive, so that the phenotypes corresponding to AO and BO are A and B, respectively.

The following diagrams illustrate transmission of hereditary group factors: mating, parents' genotypes, zygotes, and phenotypes of children with respect to blood groups A and B, blood types M and N, and the Rh factor. For a fuller discussion of the heredity of the Rh factor refer to pages 1048, 1052 to 1054.

THE MEDICOLEGAL ASPECTS OF BLOOD GROUPING

It must be accepted that the specific agglutinating attribute of the red blood cells, the isoagglutinin, and the specific agglutinating power of the serum, the isoagglutinin, when once fully developed and established, persist in the blood of individuals without changing group throughout life, and this basic fact constitutes a test in a forensic way for the examination of blood stains and in disproving the possibility of paternity in certain disputed cases.

The use of this test for forensic purposes has certain limitations. We know that 87 per cent of the cases fall in groups O and A, and only 13 per cent in Groups B and AB. The tendency of the test may therefore more frequently suggest innocence rather than guilt, since the blood composing a stain on a suspect's clothing and that of the true murderer may belong to the same group. The true value of the test, according to Smith and Glaister¹ is apparent when the blood stains examined are of the same group as that of the victim but of a different group from that of the blood of the suspect; such a defense may be raised that the stains upon the accused's clothing were produced by his own blood. This grouping reaction narrows down the given number of individuals from whom a given sample of blood may have been derived.

Its use for the determination of paternity is of value, for although the true father can never be definitely identified by the test, it can frequently be asserted that a certain man is not the father of the child in question, or that he might be the father of the child. A man who fails in repeated blood grouping tests can definitely, and without doubt, be eliminated as the father. The test is also of value when a child is claimed by two pairs of parents.

I. THE IDENTIFICATION OF HUMAN BLOOD STAINS

Identification of blood stains as of human origin, including tests for the A-B-O and M factors, is of great value in cases of alleged hit-and-run driving, rape, murder, etc., or wherever stains suspected of being blood are found. Specimens are received in the laboratory on a variety of objects. These must all be carefully labeled in indelible ink, and the specimens must be kept for possible later presentation in court. This work must be done only by those properly authorized to perform the tests.

The author* has pointed out the importance of maintaining the integrity of chain of evidence. All evidence should be collected by members of the laboratory staff and by no one else, and the laboratory staff must work in close harmony with the homicide squad. Material should be brought to the Director's office, routinely entered in the laboratory book of entry, with time, names, etc., all written, and receipts properly given by those who receive the specimens. Full written data must be compiled covering who brought in the specimen, the time brought in, and the date. A receipt should be given to the member of the personnel who brings in the material and that member should also make a written statement that he has brought in the material. One must be prepared to submit all this written evidence during the trial of the case.

Identifying a blood stain presents three problems. First, is the stain produced by blood? Second, if so, is this human blood? Third, to what blood group does it belong?

(a) Chemical Tests and Spectroscopic Examination

Chemical tests and spectroscopic examination will definitely establish the identity of a stain as blood or not blood.

1. The Benzidine Test.—

Make an extract of the material suspected of being blood. If this is in the form of scrapings, a very small amount of the scrapings may be used without dissolving, or it may be dissolved in physiologic saline. If the material is on cloth, cut the stained portion out and add a very small amount of saline to it. Use glassware which has never contained blood or blood products before. A control specimen must always be removed from an unstained portion, and tested along with the suspected stain. If the control portion gives a positive reaction, the test cannot be relied upon, and no further work may be done.

Make a saturated solution of benzidine (special for blood) in glacial acetic acid* by placing a small amount of the benzidine in a clean test tube, free from blood, and adding about 1 c.c. of glacial acetic acid to it. Shake vigorously. If all the crystals dissolve, add more benzidine until the acetic acid will not take up more of the solid. Add an equal volume of 3% hydrogen peroxide and mix thoroughly. If this solution turns green or blue, discard and make a fresh solution, using different glassware. The green or blue color was caused by the presence of blood in the glassware.

Place a drop of the extract of the suspected stain on a new clean glass slide and add a drop of the benzidine-glacial acetic acid mixture. A green or blue color indicates the presence of blood. Should this color fail to appear, repeat the test. If no color appears, the stain was not derived from blood and the test is terminated. If the specimen from the unstained portion of the material being examined gives a blue or green color, the test is without value and no further work may be done.

2. The Phenolphthalin Test.—See page 83.

3. Spectroscopic Examination of Blood Stains.—

Dissolve the stain in distilled water. The solution must be quite dilute.

Place the solution in a small glass chamber with parallel sides so arranged that rays of light will pass directly through it.

Place the chamber containing the dissolved stain in the spectroscope and adjust the instrument so that the spectrum is clearly visible. The blood will absorb some of the light rays from the spectrum, producing characteristic "absorption bands," which vary with the type of blood pigment present.

Oxyhemoglobin: 2 bands in the yellow between the Fraunhofer lines D and E.

Hemoglobin: A broad band between D and E, with a small rim over D on the red side.

Carboxyhemoglobin: Similar to oxyhemoglobin. Addition of ammonium sulphide reduces oxyhemoglobin to hemoglobin, but leaves carboxyhemoglobin unchanged.

Methemoglobin: A dark band in the red between C and D, but nearer C. If the solution is diluted properly, it splits into bands resembling acid hematin.

Acid hematin: A sharp band between C and D, nearer to C, and a broad band, not clearly defined, between D and F.

Alkaline hematin: A band between C and D. It also absorbs the violet end of the spectrum.

Hemochromogen: A sharp, dark band between D and E, and a pale, broader band over E.

Hematoporphyrin in alkaline solutions: A faint line between C and D, a broader band at D, and extending toward E, a band between D and E but nearly at E, and a broad band between E and F.

*The benzidine dehydrochloride test (page 84) may be used.

Old stains, when diluted, give hemoglobin and oxyhemoglobin bands. If a weak alkali is added, alkaline hematin is formed. If a weak acid is added, acid hematin is formed. Old and decomposed stains yield positive tests for hematoporphyrin. Add strong alkali to a portion of the blood solution to obtain alkaline hematoporphyrin bands.

Fresh blood shows oxyhemoglobin bands. Add a weak solution of ammonium sulphide to obtain the spectrum of hemoglobin. Add a dilute sodium hydroxide solution for hemochromogen bands. These two tests prove the presence of blood and also eliminate substances of vegetable and animal origin with spectra similar to that of oxyhemoglobin.

(b) Species Identification: The Precipitin Test

The principle of the precipitin test is based upon the work of Kraus who showed that, by immunizing a rabbit with injections of a culture of a bacterium, one could obtain a serum which, when added to a filtered culture of that bacterium, produces a precipitate in it.

Bordet¹ and Gengou² went further in carrying out this immunization experiment. Uhlenhuth worked out the same principle in relation to the precipitin test and its value as a medicolegal procedure. He injected rabbits with human blood and tested the antiserum on nineteen different bloods, finding a positive reaction only with human blood. Uhlenhuth³ published his tests on blood-stained articles such as sticks, sand, cotton, trousers, hatchet, etc. He showed that the antiserum made by injecting rabbits with human blood acted only with suspected human blood and that antiserum injected with pig's blood reacted only with pig's blood, etc. In other words, a precipitation occurs in the blood when in contact with homologous blood. Perhaps the most exhaustive of all these works was done by Nuttall⁴ who examined sera of all animals of any importance on the face of the globe.

Nuttall,⁴ in 1904, gave a classical account of blood relationships by means of the precipitin test. His work was done primarily to show that a common property exists in the blood of certain groups of animals, a property that has persisted throughout the ages which elapsed during our possible evolution from a common ancestor. He placed Man and Apes in one order, based on this work, the Anthropeidea.

Since the publication of Nuttall's book in 1904 and the present time, there have been occasional references in the literature on the specificity of the precipitin test.⁵ Gradwohl⁶ found that chimpanzee blood gave a ring reaction identical to that given by human blood, with antihuman precipitin serum, and that human blood gave an identical ring reaction with antichimpanzee precipitin serum. He further showed⁷ the same results using blood from the gorilla and the olive baboon (*Papio anubis*).

In other words, using the "ring" precipitin test, it is impossible to differentiate the bloods of these three primates and man. Duncan-Taylor and Gordon,⁸ by special alum absorption methods, believe that it is possible to

⁸Duncan-Taylor and Gordon: See Gradwohl: Legal Medicine loc. cit.

produce a precipitin serum which will exclude the blood of primates when the "ring" test is made. Their method is given on page 1166. Gordon also examines blood stain extracts against an ox serum-absorbed antihuman precipitin serum, to establish that it is primate blood, but this absorbed serum is of a very poor potency.

There is no simple, practicable method available at present to distinguish between the blood stains of man and the primates (apes, monkeys including baboons, lemurs or nagapie).

There are two principal methods of carrying out the precipitin test: the ring test technic, and the flocculation test. The precipitins which are formed in animals by the injection of human blood are precipitins not for blood only, but for human protein. It is for this reason that this test can be used not only for the identification of blood but also for seminal stains, bone fragments, and meat adulteration.

It is very important that the antiserum which is to be used in the test be made properly and be tested on sufficient numbers of known positives to warrant its use in a given medicolegal procedure. These antisera react with groups of mammalian bloods and so in order to single out an individual of the mammalian group, one must resort to high dilutions. By high dilutions, is meant that the antiserum must be very potent and the material under investigation extremely well diluted for the actual test.

The use of a reliable antiserum is, of course, one of the most important considerations in making this test. Either prepare these antisera in the laboratory or purchase them from reliable biological houses. The latter method is probably better for those who do only an occasional precipitin test. Since these antisera are not likely to remain potent for a long time, only a small quantity should be purchased and that quantity should be kept in an efficient icebox. In preparation of the antisera, it is best to employ a large number of animals for these immunizations, at least six. Animals may be immunized by injecting human blood daily over a period of six weeks. After this time, a quantity of blood is taken from the ear and tested with a known positive human blood. If it is effective in a high dilution, the animals are bled to the point of exsanguination under aseptic precautions, and the blood collected in a sterile manner. Blood from these animals should be taken preferably several hours after the rabbits have eaten or during a period of fasting. If blood is taken from the animal immediately after a meal, the serum is likely to be opalescent; this is highly objectionable.

An antiserum to be efficient should so act that 0.1 c.c. when added to its respective serum-antigen in a dilution of 1 to 1,000 produces a turbidity either at once or in from one to five minutes at the latest, with the formation of a distinct precipitate in from thirty to sixty minutes.

Preparation of Antihuman Precipitin Serum

The following is the method used by the author. It gives excellent results.

Select six healthy rabbits. Make 50 c.c. of a 1:10 dilution of sterile human serum or plasma in saline, by adding to 5 c.c. of human serum or plasma (obtained under sterile conditions) 45 c.c. of sterile physiologic saline; mix.

Mark each rabbit with a tag or with indelible ink for identification, and keep complete records of each rabbit and each injection. Inject 2 c.c. of the 1:10 dilution of human serum

or plasma into the marginal ear vein of each rabbit. Beginning on Monday, and continuing through Saturday, make daily injections so that a total of six injections are given to each rabbit.

Allow one week to elapse, then inject each rabbit with 2 c.c. of the 1:10 dilution of human serum or plasma *intramuscularly* (to prevent anaphylaxis), followed by daily injections for the next five days, giving these five injections intravenously, as in the first week.

Allow one week's rest interval. Repeat the six injections of 2 c.c. of 1:10 dilution of human serum or plasma, giving the first injection intramuscularly and the next five intravenously.

Wait one week. Then withdraw a small quantity of blood from each rabbit and test to determine whether any antihuman precipitin substance has been developed. In other words, carry out an actual precipitin test as described below to determine whether the rabbit's serum will detect the presence of human blood. Usually one or more of the six rabbits will show this antihuman precipitating antibody. Estimate by dilutions the potency of this precipitating antibody. Reject all rabbits' sera not reacting in at least a 1:1000 dilution. Carry out controls with both positive and negative specimens.

If one or more of these rabbits has developed an antihuman precipitin of high titer, procure the entire content of blood from the selected rabbit or rabbits by dissecting the carotid artery and bleeding into sterile 50 c.c. Rockefeller centrifuge tubes, using all sterile precautions. (See page 2040 for method of bleeding rabbit from the carotid artery.)

Label the Rockefeller tubes carefully, and allow the blood to clot in a slanting position. Loosen the clots by striking the tubes against the palm of the hand, and centrifuge at high speed for at least twenty to thirty minutes to separate the serum. With all sterile precautions, carefully decant the supernatant serum, and place in sterile corked tubes. Inactivate at 56° C. to destroy the natural complement and to kill air bacteria which may have entered the blood during the procuring process. Add enough Merthiolate as a preservative to give a 1:10,000 concentration (0.1 c.c. of a 10% solution to 100 c.c. serum).

Ampule in 1 c.c. quantities in sterile glass ampules, using sterile precautions. Seal in the flame, label with rabbit number, date, and titer and store in the refrigerator.

Technic of the Precipitin "Ring" Test

Use 5 mm. tubing with a 2 mm. bore. This is very heavy-walled narrow glass tubing. Cut it into 12 cm. lengths and seal one end in the flame. These very small caliber test tubes are used in the precipitin test. They must never have contained human blood, and must be clear and dry.

Soak the material to be examined in saline for some time. When stains have been exposed to high temperatures, it is necessary to soak as long as seventy-two hours. This extraction should be carried out in a refrigerator to avoid bacterial action and turbidity. No chemical solvents except saline should be used, regardless of how difficult it may be to obtain an extract. If the extract contains debris or is cloudy, centrifuge and use the supernatant liquid for the test or filter through a Berkefeld filter. Use a minimal quantity of saline for the extraction.

Prepare a similar extract of the *unstained portion* of the material under examination. Make the dilution about the same as that of the stained area.

Various dilutions of the extract should be used, preferably a 1:100 and 1:1,000, although higher dilutions may be made and tested if desired. Dilutions of the stain of 1:1,000 or higher will show only a scanty foam upon shaking.

Prepare a dilution of *known human serum* of approximately 1:100 strength by adding 1 drop of human serum to 5 c.c. saline.

Prepare a *negative control serum* by adding one drop of rabbit blood serum to 5 c.c. saline (1:100).

Place antihuman precipitin serum in each of five small caliber tubes described above. Add this to a depth of about 5 cm. Label the tubes as follows: (1) blood stain; (2) unstained portion; (3) known human serum; (4) rabbit serum; (5) saline.

Stratify an *equal volume* of solution from the suspected stain on the serum in the first tube; use the extract from the unstained portion in the second tube; diluted human serum

in the third tube; diluted rabbit serum in the fourth tube; and saline in the fifth tube. This is accomplished by placing the solution above the serum so that it stands about a millimeter above it, then giving it a quick flick with the finger so that the two fluids come in contact with each other but do not mix.

Allow all tubes to stand at room temperature for five minutes. Read at the end of this time, but do not report definitely until 24 hours have elapsed. Keep the tubes in a refrigerator for the 24-hour period.

If the stain contains human blood, a white line will appear at the point of contact between the two liquids. This will be definite within five minutes. Confirm twenty-four hours later by examining for a plug of precipitate at the bottom of the positive tubes.

This result cannot be relied upon unless the control tests are as follows: negative reaction in tube 2, positive in tube 3, and negative in tubes 4 and 5. Positive reactions occur from human perspiration, urine, etc.

In carrying out the test, the numerous controls must be used, all carefully marked. If the object of the test is merely to identify the suspected stain as coming from a human source, the procedure can be rapidly carried out. But if the blood is not of human origin and an opinion is desired regarding its source, it then becomes necessary to test the blood serum in turn with different antisera until a positive result is obtained.

It has been found that human blood stains dried for ten to fifteen years may still show a positive reaction. Hansemann,¹ Meyer² and Friedenthal have given accounts of their examinations of mummy tissue with the use of precipitating antisera. The first obtained a positive reaction with such material 4,000 years old, the second with tissue 5,000 years old, while the last named failed to get a positive reaction with mummy tissue 500 years old. Nuttall³ has shown that if there is a mixture of several different bloods in solution, this does not prevent a reaction from taking place between an antiserum and its homologous blood in this test. This has been confirmed by Ziemke⁴ and Smith and Glaister.⁵ The effects of heat upon blood stains have been studied; it has been found that stains subjected to a temperature of 150° C. for fifteen minutes and 200° C. for two minutes still showed a positive precipitin test. It is to be emphasized, however, that blood that has been heated in this way requires a longer time to be soaked in order to produce an extraction.

Human blood stains that have been washed in water leaving only a faint color of the blood on the garment will still show the reaction.

Boiling blood stains does not necessarily cause the reaction to disappear. Smith and Glaister⁵ subjected material to the action of boiling water for from five minutes up to one hour and it still showed a precipitin reaction following extraction with saline for a period of twenty-four hours. Stains fourteen weeks old, however, similarly treated, failed to give a positive reaction on the application of a related antiserum. One must conclude, therefore, that in case of fresh stains, boiling quickly extracts the unfixed portion of the blood serum, but in older stains the degree of fixation does not readily permit the serum to pass into solution with the water, although prolonged steeping in saline thereafter successfully extracts a sufficient quantity to yield a positive reaction.

In attempting to carry out this precipitin test on blood stains which have been soaked in soap powder, it has been found that the presence of soap powder contraindicates the use of this test for medicolegal purposes. Experiments on blood stains with various woods and leathers soaked with blood showed that the test is always reliable, provided the proper dilution is made.

Alum-Precipitated Precipitin Serum (Duncan-Taylor and Gordon)

Alum-Antigen.—

Dilute 25 c.c. of normal serum with 80 c.c. distilled water.

Add 90 c.c. of 10% potassium alum in distilled water.

Adjust the reaction to pH 6.5 with 5N sodium hydroxide solution, and centrifuge.

Wash the sediment twice with 200 c.c. of 1:10,000 Merthiolate-saline.

After centrifugalization, dilute the final precipitate to 100 c.c. with 1:10,000 Merthiolate-saline.

10 c.c. of the antigen are equivalent to 2.5 c.c. of serum.

Preparation of the Antiserum.—

Give 5 c.c. amounts intramuscularly into both hind legs of the rabbit.

Animals should weigh more than 4 kg. each and be in good condition.

Make experimental bleedings by a single puncture of the marginal ear vein on the twentieth day after injection. If sufficiently high titer is obtained, keep the animals without food for 24 hours and then bleed them from the carotid artery (page 2040), collecting the blood in sterile 50 c.c. Rockefeller tubes.

Allow the blood to clot in a slanting position, loosen the clot by striking the tube against the palm of the hand, centrifuge for about 30 minutes, and remove the serum, observing sterile precautions. Place in a sterile graduate.

Oxblood Absorption.—

Measure the serum.

Add 7% by volume ox serum to the antiserum.

Mix and maintain at room temperature for 2 hours, then place in a refrigerator at 5° C. overnight.

Centrifuge and remove the supernatant fluid.

Sterilize by filtration through a Seitz filter.

Ampule.

This alum-precipitated ox serum-absorbed antihuman precipitin serum will establish whether or not the blood stain is derived from primates, according to Gordon. When positive with ox-absorbed serum, the stain is not derived from primates.

If any of the primates is to be excluded by a precipitin test, the antihuman precipitin serum is prepared in an animal the species of which is to be excluded. Gradwohl* has reported results different from those of Taylor and Gordon, in that he obtained very little difference in the reaction of chimpanzee blood with absorbed or nonabsorbed antihuman precipitin serum. The reactions were almost indistinguishable.

Reliability of the "Ring" Test

1. A positive reaction means the presence of human blood.
2. Primate blood (chimpanzee, gorilla, olive baboon, lemur, etc.) will give an identical reaction.

*Loc. cit., Legal Medicine, p. 508.

3. Absorption of antihuman precipitin serum with oxblood does not necessarily remove the quality which gives a positive reaction with the antiserum and anthropoid blood.

The Flocculation Test for the Identification of Mammalian Bloods—The Libby Photronreflectometer (Photron'er)*

Gemeroy, Boyden, and DeFalco believe that by the use of a photronreflectometer to determine exact turbidities produced by mixing an antiserum with its corresponding antigen (antihuman precipitin serum with various dilutions of human sera), a serologic correspondence curve for that antiserum can be established, and if the serum is diluted sufficiently, it no longer reacts to a significant degree with any heterologous antigen tested against it in the native state; a different correspondence curve is established for this heterologous antigen. In other words, if an antihuman precipitin serum gives positive "ring" tests with both human and rhesus monkey bloods when the serum is not diluted, the probabilities are that it will not give powerful reactions with rhesus blood when the antiserum is diluted, although it will react strongly with human serum. In the preparation of an antiserum, it should therefore be possible to establish turbidity curves showing the type obtained with the antiserum in question and human serum, and the antiserum and other mammalian bloods. Gemeroy, Boyden, and DeFalco have conducted numerous experiments, and have produced normal titration curves of antihuman sera titrated with human, chimpanzee, and rhesus antigens. They report the serologic correspondence of the various antigens in percentage relationships with the curve produced by human serum (antigen).

To carry out this work, they use the Libby Photron'er,* which makes use of, or measures the amount of, scattered or reflected light that passes through a liquid. It is a delicate means of detecting finely suspended particles. A relatively small number of suspended particles reflects sufficient light to produce a significant reading on the galvanometer, and the greater the number of particles in suspension, the greater the amount of turbidity. A quantitative relationship can be established between the turbidity of a solution and the nitrogen content of a precipitate in protein antigen-antibody systems.

They use alum-precipitated serum for injection of rabbits. In the test, the antiserum is serially diluted with buffered saline.

Buffered Saline.—

Sodium Phosphate Solution: Dissolve 11.876 gm. of Na_2HPO_4 in distilled water and dilute to 1,000 c.c. with distilled water.

Potassium Phosphate Solution: Dissolve 9.078 gm. of KH_2PO_4 in distilled water and dilute to 1,000 c.c. with distilled water.

Add 6 c.c. of sodium phosphate solution

and 4 c.c. of potassium phosphate solution

to 50 c.c. of 0.85% sodium chloride solution, and dilute to 100 c.c. with 0.85% sodium chloride.

Serial dilutions of the serum, 1:250, 1:500, 1:1,000, 1:2,000, 1:4,000, 1:8,000, 1:16,000, 1:32,000, 1:64,000, 1:128,000, 1:256,000, and 1:512,000, are made with

*Gemeroy, A. B., and others: See Gradwohl: *Legal Medicine*, St. Louis, 1954, The C. V. Mosby Co., pp. 510 ff.

buffered saline. Each dilution is mixed with the antigen (serum being tested against the antiserum), and tested in the Photron'er. The sum of the turbidities noted from the complete reaction range of the antigen-antibody mixtures represents the precipitation capacity of the antiserum. Comparisons of total turbidities resulting from these summations represent the serologic correspondence of all the antigens tested with a single antiserum.

By making turbidity curves at various dilutions, using the antiserum against different bloods, one can determine the exact dilution of the antiserum where further dilution would practically "wipe out" any reaction with certain bloods, thereby making this reaction almost species specific. It is possible that this flocculation test may find wider use in identifying specific blood when more facts have been established. For complete details, refer to *Legal Medicine* (1.c.).

Fig. 287.—Normal titration curves when an antihuman serum is titrated with human, chimpanzee, and rhesus antigens. The serologic correspondence of these antigens is recorded in percentage relationships at the top of the figure. (From Gradwohl: *Legal Medicine*; The C. V. Mosby Co.)

(c) Blood Grouping Tests

The third problem to be solved is the determination of the group of blood to which this human blood stain belongs. For practical purposes, the investigation must be limited to a search for the A, B, O, and AB groups, and at times for the M factor. Results of attempted identification of blood stains for the Rh types are rather disappointing. The N factor disappears rapidly in dried blood, but the M factor can be found at times, so that tests for the M-N types are likewise disappointing.

Identification of the various blood factors in a dried stain is often used in forensic medicine to prove that a certain stain did *not* come from a certain individual. If, in a given case, the blood group of the suspect and that of the victim are the same, no deductions can be drawn, for the stain might have come from the suspect. One must remember that a stain on clothing may be

due to group receptors coming from the individual himself. Underclothing worn for several days is almost certain to contain A and B receptors if these are present in the blood and sweat.

But if the investigator obtains different results with the stain found on the suspect and the suspect's own blood, then evidently the stain was derived from a different individual. And if the stain has the same blood factors as the blood of the victim, it might or might not have been derived from the victim.

If liquid blood is submitted, tests are run in the same manner as those used in blood grouping for transfusions. If the blood is submitted in the form of a "crust," and this blood is fairly fresh (not more than 48 hours old), and sufficient material is submitted, the crust test may be run. Usually, however, one resorts to the agglutinin absorption test to identify blood stains.

Examination of Blood Crusts.—

Place small portions of the stain of approximately equal weight on glass slides.

Add, to one, a suspension of group A₁ cells in saline, and to the other a suspension of group B cells.

After the crust has softened, drop cover slips over the mixtures.

Apply gentle pressure intermittently to the cover slip and examine from time to time under the low power of a microscope, for a time period of about 30 minutes.

At the same time, add a suspension of group O cells to some of the crust, and treat in the same manner as for A and B cells. This is the control. These group O cells must not be agglutinated. If they are, the results of the tests are not reliable.

If A cells are agglutinated, the stain contains anti-A agglutinin; if the B cells are agglutinated, the stain contains anti-B.

TABLE 124.—POSSIBLE RESULTS WITH THE CRUST TEST

BLOOD CRUST PLUS A ₁ CELLS	BLOOD CRUST PLUS B CELLS	AGGLUTININ PRESENT	CONCLUSIONS
+	+	Anti-A Anti-B	Blood stain derived from group O individual
+	—	Anti-A	Blood derived from group B, or else failure of reaction with B cells
—	+	Anti-B	Blood derived from group A, or else failure of reaction with A cells
—	—	None	Either stain is group AB or there is lack of reaction due to disappearance of agglutinins

Agglutinin Absorption Test.*—

The agglutinin absorption test is made to determine the agglutinin content of a blood stain. When the stain is mixed with anti-A, anti-B, or anti-M serum, removal of the agglutinin present in the antiserum means the presence in the stain of the corresponding agglutinin. In other words, agglutinin "A" will absorb agglutinin anti-A, agglutinin "B" will absorb anti-B, etc. Anti-A serum normally agglutinates cells containing the agglutinin "A"; therefore, if these cells are added to the antiserum which has been subjected to absorption by the stain, and the "A" cells do not agglutinate, the stain has removed the anti-A agglutinin from the antiserum. This proves that the stain contains "A" agglutinin. This principle is true for anti-B and anti-M sera.

*These tests can be made on gastric contents, semen, etc.

Since the cells themselves cannot be recovered from a dried blood stain, no actual blood grouping experiment can be made, and resort must be had, therefore, to the agglutinin absorption method.

If the blood is in the form of a crust or powder, and sufficient specimen is obtainable, grind it into very fine powder, and add 10 mg. portions to 0.1 c.c. of each testing serum (anti-**A**, anti-**B**, and anti-**M**) in small tubes.

Mix thoroughly with the aid of a stirring rod and then allow it to stand in a refrigerator overnight to complete the absorption. Centrifuge and test the supernatant dark-red fluid for its agglutinin content (see above).

If the material has been absorbed, as it will be on clothing, paper, and other articles, cut out portions of the stained and also the unstained areas, of approximately equal size, and use these for the tests. It is essential that controls be run, using material from the unstained portion of material, since this at times contains one or both of the blood group receptors, from sweat, urine, or animal material. If the tests for the receptors in the unstained material are positive, the results obtained in tests on the stained area cannot be relied upon.

Use glassware and equipment which contains no blood or body secretions. Never touch any of the material with the bare hand. Always mark the portion of specimen from which the stain and the unstained areas have been cut, using an indelible pencil, for possible later identification in court.

Material Needed.—

Have on hand anti-**A**, anti-**B**, and anti-**M** testing sera with titers not to exceed 1:8 or 1:16. If the titers are higher than this, make appropriate dilutions.

There must also be saline suspensions of group **A**, **B**, and **OM** cells.

Technic.—

Cut out portions of both stained and unstained material of approximately equal size, and place in separate small Kahn tubes. Use three tubes for the stained portion and three for the unstained portion.

To each tube 1, add anti-**A** serum, only as much as the specimen will absorb after prodding with a narrow stirring rod.

Add anti-**B** serum to each tube 2, and anti-**M** serum to each tube 3.

Place in a refrigerator overnight. Enough serum can be recovered for the tests by pressing the tip of a capillary dropper against the material and sucking up with a rubber bulb. Tests and controls are run simultaneously, as in Table 125.

TABLE 125

TUBE 1	2	3	4	5	6
Anti- A serum plus Stain	Anti- A serum plus Unstained	Anti- B serum plus Stain	Anti- B serum plus Unstained	Anti- M serum plus Stain	Anti- M serum plus Unstained

Place in a refrigerator overnight.

The following day, express serum as directed above, using a capillary dropper, and test against cells as directed in Table 126. Carry out the tests on ring slides (Boerner).

Add the opposing cells to the serum subjected to absorption, rotate for 5 to 10 minutes, and examine under the low power of a microscope. Report agglutination as positive and lack of agglutination as negative.

Rings 2, 8, and 10 must show agglutination: Anti-**A** serum plus unstained material, plus **A** cells; anti-**B** serum plus unstained material, plus **B** cells; and anti-**M** serum plus unstained material plus **M** cells. These controls must always be positive.

Rings 3, 4, 5, and 6 must always be negative: anti-**B** serum plus **A** cells, anti-**A** serum plus **B** cells.

Rings 1, 7, and 9 are the test rings, the others being controls. See Table 127.

TABLE 127.—RESULTS POSSIBLE IN THE TEST

RING 1	RING 7	RING 9	
Extract from	Extract from	Extract from	
tube 1	tube 3	tube 5	
⁺	⁺	⁺	
A cells	B cells	M cells	CONCLUSIONS
-	-		Stain contained both A and B agglu- tinogens, which removed anti-A from tube 1 and anti-B from tube 3: Stain belongs to group AB*
-	+		Stain removed anti-A from tube 1 and therefore contained "A" agglu- tinogen. It did not remove anti-B from tube 3 and therefore did not contain "B" agglutininogen. Stain is group A (or it might have failed to absorb the anti-B, in which case it would be AB). Stain contains the "A" agglutininogen
+	-		Stain did not remove anti-A from tube 1 but did remove anti-B from tube 3. The stain contained only "B" agglutininogen, or else failed to ab- sorb the anti-A. In the first case, it is derived from group B indi- vidual. It contains "B" agglu- tinogen
+	+		Stain removed neither anti-A nor anti- B and therefore contained no ag- glutininogen, group O, or else there was failure of absorption
		-	Stain removed anti-M and therefore contained M agglutininogen
		+	Stain failed to remove anti-M and thus either does not contain M agglutininogen or else there was failure of absorption

*This is always a dangerous diagnosis to make because of the possibility of non-specific absorption.

One must remember that these are methods for detecting indirectly the presence of certain agglutinogens in a blood stain, and are not direct tests for blood groups as entities. One may state that a stain contained a certain agglutininogen, but not that a certain agglutininogen was not present.

BLOOD GROUPING TESTS IN THE EXCLUSION OF PATERNITY

Since the agglutinogens O, A, B, M, N, Rh, and Hr are inherited, blood grouping can be applied to the problem of paternity. There are certain fundamental facts on which this statement is made. First, agglutinogens A and B or any others cannot appear in the blood of a child unless present in the blood of one or both parents. Second, an AB parent cannot give rise to a group O child, nor can an O parent give rise to an AB child. According to our present knowledge, there are 288 different combinations of blood groups, so the problem of determination of parentage by blood grouping has been greatly elaborated. Both cells and serum of each individual should be examined, together with the usual control tests. In Tables 122 and 123 will be found a summary of the hereditary facts of A, B, M, N, and Rh, with the possibility of blood groups in children of all the matings and also the offspring not possible.

While it is true that isoagglutinins are not fully developed until the child is several months old, the blood group can be determined from the agglutinogens in all cases. Wiener gives the following examples of cases in which blood grouping may prove of value: (1) in cases of children born out of lawful wedlock where the husbands deny paternity; (2) in cases where children are born out of lawful wedlock and the men named by the mothers as their fathers deny paternity; (3) in cases where newborn infants have been accidentally interchanged in the hospital and it is necessary to identify the parents of the infants; or where a wet nurse has willfully substituted her own infant for the one placed in her custody; (4) in cases where women have simulated pregnancy and childbirth in order to compel men to marry them or to obtain dower rights in the deceased husbands' estates.

Blood grouping is of value only for excluding paternity. With our present knowledge paternity cannot be definitely proved. It may be difficult or even impossible at times to establish the innocence of a putative father falsely accused. For example, if both the mother and the infant are group O MN and the putative father is group OMN, no conclusions can be drawn except that the accused could be the father of the child. If, however, he is group AB, he is at once exonerated, since no AB individual can be the parent of a group O child.

It is to be borne in mind that there are many different combinations or kinds of blood obtainable. Wiener¹ has shown by utilizing the four major blood groups, O, B, A, and AB, with subgroups of A and AB; the three blood types M, N, and MN; and the eight Rh blood types, it is now possible to distinguish 144 different kinds of human blood instead of the original four groups. There are six groups, O, A₁, A₂, B, A₁B and A₂B. There are three blood types, M, N, and MN, and two types due to the absence or presence of factor P. By multiplying together the number of subgroups of each of the above, as well as the eight Rh types, namely, $6 \times 3 \times 8$, the figure 144 is obtained. If the **hr'** and **hr''** factors are also utilized, the number is even greater. Only a few contributions

¹Wiener, A. S.: *Blood Groups in Blood Transfusion*, ed. 3, Springfield, Ill., 1943, Charles C Thomas, Publisher.

on the subject simultaneously utilizing the three blood group systems have appeared in the literature, namely, by Wiener,² by Alvarez,³ and the most recent by Unger.⁴ (Note: The **P** factor is not used in paternity cases.)

The following cases in our service* illustrate the manner of using blood grouping tests for A-B and M-N factors in cases of disputed paternity.

Case 1. This was a case in which the husband feared that he was not the father of his 4-year-old child, although he stated that he had no reason to doubt the faithfulness of his wife. The father wanted this test carried out because one of his friends, evidently a trouble maker, had suggested to him in a bantering manner that he might not be the father of his child. This caused him such mental unrest that he determined to have the tests made to ease his mind. Fortunately, we were able to accomplish this purpose.

The mother, child, and husband were tested in the usual manner for blood groups A-B, and Types M-N. The results of the tests were as follows:

Mother was OMN

Child was A₂N

Father was A₂BN

With this rather rare combination of blood groups, it was very easy to state that this man could have been the father of the child, although, as stated above, actual paternity cannot be definitely proved by these tests. Since the child possessed the agglutinin N, which was present also in the mother's blood, the father must necessarily have had agglutinin N in his erythrocytes. With a group O mother and a group A₂B father, the children will be either A₂ or B, but not O or A₂B. (See Table 122.)

Genetics for this case would be expressed as follows:

Mating O and A₂B

Children possible: — A₂-B-MN-N

Mating MN and N

Children not possible: — O-A₁-A₁B-A₂B-M

Case 2.—This was a case of an unmarried mother, whose blood group was OM. The putative father denied the charges of paternity but was willing to submit to having tests made of his blood. The baby in this case was group OMN. Tests of the man's blood showed him to be Group OM. In this instance, the factors A-B were not conclusive evidence of paternity, but the types M-N showed definitely that the man in question could not be the father of the child. He was, therefore, relieved of the responsibility of supporting a child which was not his own. If the mother is type M, and the child is type MN, the father must be either type N or MN (consult Table 122), for he must have the N agglutinin in his erythrocytes.

Had the man in this case been Type N or MN, then the laboratory tests would have proved nothing beyond the fact that he could have been the father of the child.

*Gradwohl Laboratories, St. Louis, Mo.

²Wiener and Sonn: J. Lab. & Clin. Med. 30: 395, 1945. Wiener: Am. J. Clin. Path. 16: 477, 1946.

³Alvarez: Bol. Asoc. Med. Santiago 6: 463, 1948.

⁴Unger: J.A.M.A. 152: 1006, 1953.

Genetics for this case are as follows:

Mating O and O

Children possible: — O — M

Mating M and M

Children not possible: — A₁-A₂-B-A₁B-A₂B-N-MN

According to the work of Landsteiner and Wiener,¹ it has been shown that the property Rh is not a sex-linked dominant factor. This follows first from the equal distribution of the factor in the two sexes, and second, from the analysis of families in which the father is positive and the mother is negative, where on the usual hypothesis only the offspring of one sex, most probably the daughters, would exhibit the character.

Facts Concerning the Heredity of Blood Groups.—

The M factor cannot appear in a child unless it is present in the parent; similarly, the N factor must be present in a parent in order to appear in a child.

If a child is an M type, the M factor must have been present in both parents. If the child is type N, the N factor was present in both parents.

If one or both parents are M, the offspring cannot be type N.

If either or both parents are N, the children cannot be type M.

An AB individual cannot be the parent of an O child.

An O individual cannot be the parent of an AB child.

The erythrocytic structures A and B are found in children only if present in the parents.

If this structure is absent in the parents, it is never present in the children.

If both parents have a definite blood structure, it usually appears in all the children; however, it may be absent in some.

If only father or mother possesses a definite structure, it is usually found in some of the children, but it may be found in all.

For instance, if a child has A erythrocytes, but the mother has no A factor in her cells, then the father must have A erythrocytes. If the father has no A erythrocytes, but he has O or B corpuscles, his parenthood is disproved.

From a medical standpoint we have been long interested in the problem of possible exceptions to this rule. A Prussian court stated: "if 2,000 children were examined and 1 exception would be found, this court would doubt the reliability of blood typing." The obstacles to the legal recognition of blood typing are removed. On the basis of blood findings of mother and child and the presumed father, it has been proved that it is apparently impossible

¹Landsteiner, K., and Wiener, A. S.: J. Exper. Med. 74: 309, 1941.

that X is the father of the child, or else the fatherhood of X is possible but cannot be proved positively. Another man of the same blood group could be the father. A diagnosis based on blood groups may, therefore, lead to the exclusion of fatherhood but it cannot yield results in a positive sense. If, in addition to A and B, we take blood properties M or N into consideration, according to Schiff, we can recognize serologically every third "non-father."

When the A-B-O, M-N, and Rh-Hr blood group systems are simultaneously utilized, Unger² states that there is an approximate 50 per cent chance of excluding a falsely accused man of being the father of a given child.

Technic of Blood Grouping Tests for the Exclusion of Paternity

All tests are made in duplicate, using two sets of antisera from two different manufacturing sources. If these are not available, then use two sets of antisera from the same manufacturer, but from different batches of sera. All tests must be read by two different people, without knowledge of the results obtained by one another (the "blind" test of Wiener).

It is necessary to have blood specimens from (a) the mother, (b) the baby, and (c) the putative father.

No Rh-Hr sensitivity tests need be made on these bloods.

Clotted blood is used for obtaining serum. Loosen the clot, centrifuge, and remove the supernatant serum, placing it in a properly labeled tube. Do this for all three bloods.

Liquid blood is obtained by taking the blood in the special dry anticoagulant (page 1005) and shaking to prevent clotting. The supernatant plasma may be used if no clotted blood has been submitted, but results are more clear-cut with serum than with plasma.

If only clotted blood is submitted, the 2 per cent cell suspension in saline and the 50 per cent cell suspension in their own plasma or serum must be made from the clot after the serum has been removed. Shake some of the cells loose from the clot in the serum, and centrifuge. Remove enough serum to leave a 50 per cent concentration of cells. Prepare the 2 per cent saline suspension from the clot by shaking the cells free into saline.

If blood is taken in an anticoagulant, prepare the cell suspensions as outlined on page 1005.

Wash the saline-suspended cells once with saline, and resuspend to a 2 per cent concentration in saline.

The following antisera will be needed:

Anti-A	Anti-Rh ₀ saline agglutinating
Anti-B	Anti-Rh ₀ slide test (blocking)
Absorbed anti-A	anti-hr' saline agglutinating*
Anti-M	anti-hr'' saline agglutinating (if
Anti-N	available)*
Anti-rh' saline agglutinating	anti-hr' slide test (blocking)*
Anti-rh'' saline agglutinating	anti-hr'' slide test (blocking)*

*Either the saline agglutinating serum or the slide test serum may be used. It is not necessary to use both.

²Unger, L. J.: J.A.M.A. 152: 1006, 1953.

The following tests are made of all the blood specimens: mother's, father's, and baby's. (See Fig. 288, *A* and *B*.)

1. Test the cells for A-B-O groups by mixing the cells with anti-**A** and also anti-**B** sera of high potency. At the same time, make controls on the antisera. Exact technic is given on page 1012.

2. Check the results in (1) by testing the serum or plasma against known A and B cells suspended in saline. If different results are obtained in these two tests, an error has been made and the tests must be repeated, using different antisera. If isohemolysis occurs, and the results cannot be easily read, inactivate the serum, cool to room temperature, and repeat the test.

Fig. 288A.—Setup for blood-grouping tests in determination of paternity.

3. Subgroup all A's and AB's by using the cell suspensions against absorbed anti-**A** serum (anti-**A**₁) on which proper controls have been made. See page 1018.

4. Test the cells against anti-**M** and anti-**N** sera on which controls have been run. This gives the M-N types (see page 1144).

5. Make tube agglutinating tests for the **Rh** and **Hr** factors and the **Rh**₀ variant:

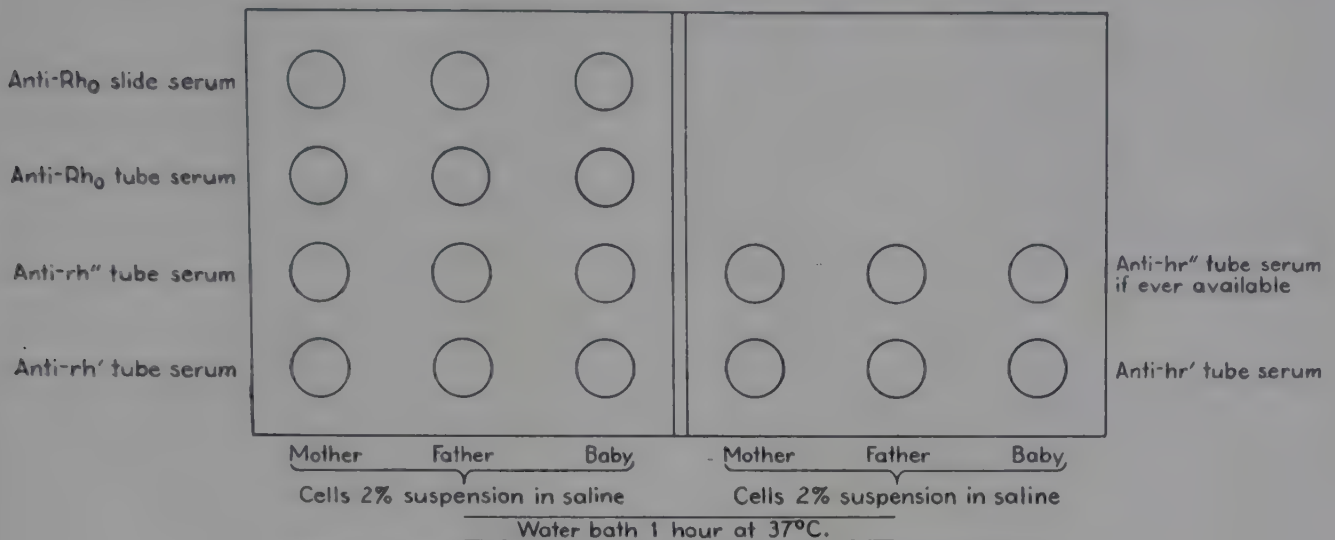

- | | |
|--------------------------------------|---|
| (a) 1 drop of saline-suspended cells | plus 1 drop anti-rh' saline agglutinating serum |
| (b) 1 drop of saline-suspended cells | plus 1 drop of anti-rh'' saline agglutinating serum |
| (c) 1 drop of saline-suspended cells | plus 1 drop of anti-Rh ₀ saline agglutinating serum |
| (d) 1 drop of saline-suspended cells | plus 1 drop of anti-Rh ₀ slide test (blocking) serum |

- (e)* 1 drop of saline-suspended cells plus 1 drop of anti-hr' saline agglutinating serum
- (f)† 1 drop of saline-suspended cells plus 1 drop of anti-hr'' saline agglutinating serum (when available)

Incubate in a water bath at 37° C. for 1 hour.

Take bottom readings. See page 1058.

SET-UP FOR BLOOD GROUPING TESTS IN CASES OF DISPUTED PATERNITY

When Anti-Rh₀ tube serum gives a negative result, wash contents of tube 4 (Anti-Rh₀ slide serum) three times with saline, remove saline, shake, replace in water bath 5 minutes, add 1 drop of Coombs serum, shake, centrifuge 2 minutes at 500 to 1000 r.p.m., and read. If positive, Rh₀ is present.

Fig. 288B.

*Not necessary when blood is rh'-negative: reaction would be positive.

†Not necessary when blood is rh''-negative: reaction would always be positive.

Read under a scanning lens of a microscope and report all clumping as positive and lack of clumping as negative.

If the results with the anti-Rh₀ saline agglutinating serum are negative, use tube 4 containing the cells plus anti-Rh₀ slide test serum. Wash three times with saline and then remove all traces of saline (see page 1058). Shake; incubate at 37° C. for 5 minutes in a water bath, and add 1 drop of Coombs serum (antiglobulin), centrifuge for 2 minutes at 500 to 1,000 r.p.m., and read the reaction under a scanning lens. Do not perform this test if the results with anti-Rh₀ saline agglutinating serum are positive because this would always be positive.

6. Make a test for the Hr factors by the slide method. Use 2 drops of whole blood (50 per cent cell suspension in their own serum or plasma) and 1 drop of the respective anti-hr' or anti-hr'' sera.*†

Mix and spread each with a wooden applicator.

Read over a lighted viewing box, preheated for 30 minutes. Rock back and forth for 3 to 5 minutes.

Add a drop of saline and rock back and forth to eliminate rouleaux formation.

Do not make the 'anti-hr' test on Rh-negative bloods, because this test would always be positive under the circumstances. Whenever the test for rh' is positive, make the test for hr'. Similarly, only when the test for rh'' is positive, make the test for hr''. All Rh-negative bloods are hr'-positive and hr''-positive.

7. Record the results according to Table 128. Draw conclusions as to phenotype and genotype according to Wiener's Table 111 on page 1053. Table 128 is given here as an example.

It must be remembered that it is never necessary to make tests for hr' if rh' is absent from the blood. Similarly, it is not necessary to make tests for

TABLE 128

5.			

Interpretation:

Respectfully submitted,

ALEXANDER S. WIENER, M.D.

LAWS OF HEREDITY

- I. The Blood Groups (O, A, B, and AB)
 - 1. The agglutinogens A and B cannot appear in the blood of a child unless present in the blood of one or both parents.
 - 2. Group AB parents cannot have group O children, and group O parents cannot have group AB children.
- II. The Blood Types (M, N and MN)
 - 1. The agglutinogens M and N cannot appear in the blood of a child unless present in the blood of one or both parents.
 - 2. Type M parents cannot have type N children, and type N parents cannot have type M children.
- III. The Subgroups of Group A (A₁ and A₂) and Group AB (A₁B and A₂B)
 - 1. No child can belong to subgroup A₁ or subgroup A₁B unless one or both parents belongs to one of these subgroups. For example, two parents both of subgroup A₂ cannot have a child of subgroup A₁.
 - 2. Parents of subgroup A₁B cannot have children of subgroup A₂, and parents of subgroup A₂ cannot have children of subgroup A₁B.
 - N. B. When a man is excluded by these tests, it is highly probable, though not absolutely certain, that he is not the father of the child in question.
- IV. The Rh Blood Types [rh, rh', rh'', rh'rh'' (or rh₇), Rh₀, Rh₁ (or Rh₀'), Rh₂ (or Rh₀'') and Rh₁Rh₂ (or Rh_z)]
The Hr Factors: Rh₁Rh₁ = Rh₁ hr' -, Rh₁rh = Rh₁ hr' + rh'rh' = rh' hr' -, rh'rh = rh' hr' +
Rh₂Rh₂ = Rh₂ hr'' -, Rh₂rh = Rh₂ hr'' + rh''rh'' = rh'' hr'' -, rh''rh = rh'' hr'' +
 - 1. Factors Rh₀, rh', rh'', hr' and hr'' cannot appear in the blood of a child unless present in the blood of one or both parents.
 - 2. Parents who are rh' negative cannot have children who are hr' negative, and hr' negative parents cannot have rh' negative children.

MEDICOLEGAL ASPECTS OF BLOOD TRANSFUSION

This chapter cannot be closed before considerable attention is paid to an important report by the Committee on Medicolegal Problems of the American Medical Association.¹ This Committee was composed of Alexander S. Wiener, Chairman, and David N. W. Grant, Lester J. Unger, and William G. Workman. They represent a group of outstanding serologists with a vast experience in this field. The following remarks are based largely upon this Report, and while at this time (1956) the material is authoritative, one cannot predict from the rapid strides that are now being made whether or not in the future they will necessarily be modified.

The report states that approximately one death in 1,000 to 3,000 transfusions has been reported. This makes blood transfusion as important a cause of death as appendicitis or anesthesia.

Errors are frequently made during emergency periods when the regular technician is not at hand, where a certain number of errors are inevitable. They advise that all hospitals should carry liability insurance and that medical schools should devote more attention to blood grouping in their curricula.

Unfavorable results have occurred because blood grouping sera have been inadvertently interchanged; also, when two patients require transfusions at the same time and the bottles of blood intended for them have been interchanged. In a few cases, errors have resulted because the wrong pilot tube was affixed to a bottle of blood. Most transfusion accidents due to mixing up of bloods can be traced to a failure to read labels. Colored grouping sera and labels have the disadvantage that the technician has a tendency to rely on his memory of the colors instead of reading the labels on the bottle of blood.

If a patient dies as a result of a transfusion of blood of an incorrect group, or suffers prolonged illness due to injury to his kidneys, the patient's family or the patient himself, if he survives, may be entitled to damages.

One of the commonest causes of hemolytic reactions is the transfusion of blood of an incompatible blood group.

Anti-A and anti-B isoantibodies in human sera are generally of low titer and avidity, and, if so, an initial transfusion of group A blood to a group O individual might be uneventful or produce only a slight reaction. As a result of such a transfusion of incompatible blood, the isoantibody titer will rise, so that if the error is repeated a fatal reaction could result.

The severity of the reaction in strongly sensitized individuals depends on the amount of blood transfused, fatalities in adults being infrequent with quantities of blood less than 300 c.c. Therefore, if this portion of each unit of blood is given slowly and the patient watched closely during that time for untoward symptoms, it may be possible to interrupt the transfusion in time, should a reaction develop. This cannot occur in patients under anesthesia.

¹J.A.M.A. 151: 1435, 1953.

Subgroups of A

The A_2 agglutinin is characterized by its weaker reaction with anti-A serum. The reactions are especially weak in the presence of agglutinin B, so that blood of subgroup A_2B has often been incorrectly classified as group B. The low avidity of most anti-A sera for A_2B blood which is responsible for errors in blood grouping also protects the patient receiving such incompatible blood from any dangerous reaction.

The Rh Factor

For blood transfusion practice, it is sufficient to limit the tests on patients to only one of the Rh-Hr factors, Rh_0 , the factor which corresponds to the one originally discovered with the aid of anti-rhesus immune animal sera. Generally, the initial transfusion of Rh-positive blood into an Rh-negative recipient is symptomless. In individuals who have been previously sensitized as a result of an injection of Rh-positive blood or a pregnancy with an Rh-positive fetus, even the first transfusion of Rh-positive blood can cause a severe reaction.

By carrying out cross-matching tests by the modern technics, namely, the saline, the conglutination, and the antiglobulin methods, incompatibilities with respect to the other factors of the Rh-Hr systems can be detected should isosensitization be present.

Persons with blood possessing an Rh_0 variant may be incorrectly classified as Rh-negative. A transfusion of blood containing an Rh_0 variant into an Rh-negative recipient can give rise to isosensitization.

Under certain conditions, Rh-negative blood may seem to react as Rh-positive. For instance, if bloods from pregnant women are tested by the slide technic, rouleaux formation, which often occurs in pregnancy, may be mistaken for clumping. In acquired hemolytic anemia, the red blood cells may be coated with autoantibodies, which may be responsible for clumping in tests carried out by the conglutination method.

In most cases of transfusion reactions where Rh-positive blood is transfused to Rh-negative individuals, the error can be traced to some laboratory error rather than a peculiarity in the blood itself. A hemolytic reaction occurring after a transfusion of Rh-positive blood into an Rh-negative patient is usually evidence of negligence.

The selection of donors is no longer a simple process. Any blood bank and hospital where blood transfusions are carried out should have a specially trained technician to handle the work under qualified medical supervision. The dangers of transfusion have been summarized by Unger² and Wiener.³

Universal Donors

While transfusion of group A blood into a group O recipient may cause a serious reaction, the transfusion of group O blood into a group A recipient is generally harmless. In the former case, the small volume of incompatible

²Unger, L. J.: New York M. J., May 1954.

³Wiener, A. S.: J. A. M. A. 150: 1301, 1954.

donor's cells combines with the isoantibodies present in a much larger volume of the recipient's plasma, while in the latter instance a limited amount of incompatible donor's plasma is diluted in the recipient's circulation and absorbed by the great mass of the patient's red blood cells. Blood containing incompatible agglutinins is much less dangerous than blood containing incompatible agglutinogens.

Transfusions of group O blood into individuals of other groups may be dangerous. Hemolysis may follow such transfusions when the donor has isoagglutinins of high titer in his serum. While injection of high-titered group O blood into individuals not belonging to group O may produce an acute hemolytic reaction, the symptoms are usually somewhat different from those which occur when incompatible red blood cells are injected. The use of group O blood as "universal donor" blood should be restricted to emergencies where there is not enough time to determine the group of the recipient reliably.

If it is not always possible to carry out all the tests necessary in cases of emergency, that is, tests relative to the Rh factor, preferably low-titer group O Rh-negative blood should be used for transfusions, especially in women during the child-bearing period. One must balance the danger of hemorrhage against the danger of isosensitization. A suitable entry should be made on the patient's chart to justify the course of action taken.

The transfusion of Rh-negative blood of the proper blood group into an Rh-positive recipient is almost always safe. Careful cross-matching tests must be done to detect incompatibilities aside from those due to the **Rh₀** factor (Rh subtypes, Hr, etc.).

Other Blood Groups

The sera of certain rare individuals contain irregular isoantibodies for blood group factors other than A and B, for instance, anti-**M**, anti-**P**, and anti-*Lewis*. In addition, immune antibodies to blood factors besides Rh-Hr may be formed as a result of isosensitization, notably anti-**M**, anti-*Kell*, and anti-*Duffy*. This may cause serious hemolytic reactions.

The Committee does not believe that reactions caused by sensitizations to one of the other blood factors can properly be a cause of action for a lawsuit, provided that the physician and hospital have exercised ordinary care to protect the welfare of the patient.

Damaged Blood

Blood damaged during storage may break down rapidly in the patient's circulation and give rise to hemoglobin nephrosis. No blood should be used if, after inspection, hemolysis is suspected.

Red blood cells are sensitive to freezing and overheating. Dry ice must not be used. No attempt should be made to warm blood prior to or during its administration. Blood stored too long or improperly can give rise to transfusion hemolysis. The National Institutes of Health permit an expiration date of 21 days for blood stored in citric acid-dextrose solution.

Blood should be kept cold from the moment it is collected until it is used. It should be stored in a refrigerator set preferably at 4° to 6° C. The temperature of the refrigerator must be recorded at least once a day.

Transmission of Disease

One of the most serious dangers is transmitting homologous serum hepatitis to the patient. This may occur once among 200 patients receiving transfusions, and may be responsible for the patient's death once among 6,000 transfusions. The danger is graver following plasma transfusion.

Homologous serum hepatitis was observed during World War II as a result of the extensive use of pooled dried plasma when treating battle casualties. Pooling increases the hazard of homologous serum hepatitis, because the presence of the virus in a single sample of blood plasma will serve to contaminate the entire pool. The most important difference between homologous serum hepatitis and infectious hepatitis, or catarrhal jaundice, is the mode of transmission. There is no simple test by which the carrier of the virus can be recognized, and the presence of the virus in the plasma pool can be detected only by testing it on human volunteers.

The National Institutes of Health have required that pooled plasma be irradiated before distribution, and this ruling is still in effect. Recent observations, however, indicate that such irradiation may not always be effective. Irradiation is not applicable to whole blood. The problem of homologous serum hepatitis has not yet been solved.

Syphilis

Transmission of syphilis by transfusion is rarely heard of any longer.* This is mainly due to the development of more sensitive tests for the detection of the disease in prospective donors, while another effective factor in preventing the disease is the widespread use of bank blood. According to this report: "Since the agent of this disease cannot live more than a few days outside the body, even at refrigerator temperature, the danger of transmitting syphilis is virtually nonexistent when blood or plasma aged for at least three days is used for transfusions." *No individual with positive serologic tests for syphilis or positive history of the disease should be used as a donor.*

Malaria

Transmission of malaria by transfusion is a difficult problem in regions where the disease is endemic, but until recently it was not an important problem in the United States. For obtaining fresh blood for transfusion, individuals who have had malaria or who have received suppressive therapy for malaria while residing in a malarious region should not be used as donors for a period of at least two years following the last proved attack of discontinu-

*Elsewhere in this chapter (pages 1086 ff.) will be found the author's own views on this subject. His views are based upon experiences, not with blood bank blood, but with fresh blood from individual donors.

ance of suppressive therapy. The *Plasmodium malariae* can survive in a refrigerator for as long as five days, so that bank blood less than five days old might be infectious.

Other Infectious Diseases

Other infectious diseases, such as measles and influenza, have been transmitted by blood transfusion, when the donor was in the prodromal stage of the disease at the time his blood was used for transfusion. All prospective donors should be examined to detect the presence of infectious disease.

Contaminated Blood

Bacteriologic surveys have shown that as many as 5 to 10 per cent of bank blood specimens are contaminated with bacteria. No harm results usually, because the majority of microorganisms present are gram-positive bacteria relatively low in pyrogenicity, do not grow at refrigerator temperature, and are generally nonpathogenic. Some bacteria grow at refrigerator temperature.* Transfusion of such blood has resulted in death of the patient. At this time it is not considered advisable to add any antiseptic to blood in an attempt to prevent bacterial growth. Prime reliance must be placed on stringent aseptic technic when collecting and storing blood.

Other Accidents Following Transfusion

Embolism.—During storage of blood or plasma, precipitation of fibrin gradually occurs, and if such blood or plasma is transfused unfiltered, multiple embolization into the lung bed may occur, or, if the recipient has a cardiac septal defect, into the viscera or brain. All bank blood and stored blood should be filtered during transfusion.

Rapid transfusion of blood by pumping air under pressure into the blood reservoir has caused a number of deaths from air embolism. This type of injection should be condemned.

Allergic Reactions.—About 1 per cent of blood transfusions are followed by reactions of an allergic type. These reactions are mild and consist merely of urticaria. Angioneurotic edema is a more serious allergic manifestation which may be dangerous if it involves the larynx. It is best not to use allergic individuals for blood donors.

Pyrogenic Reactions.—Pyrogenic reactions have been caused by growth of bacteria in the water used for preparing solutions, or in moisture adherent to the apparatus, before they are sterilized.

Methods have been developed for preparing pyrogen-free solutions and apparatus, which are readily available commercially. (See pages 1123 ff., Pyrogenicity.) Therefore, pyrogenic reactions should no longer be an important problem.

Overloading.—Too rapid transfusion or transfusion of too much blood may cause death from congestive cardiac failure or cerebral hemorrhage. A

*Stevens and associates (Ann. Int. Med. 39: 1228, 1953) reported a fatal transfusion reaction due to cold growing *Pseudomonas* sp. in stored blood.

certain number of deaths from too rapid transfusions still occur, especially when transfusions are given to infants.

Citrate Reactions.—The sodium citrate which is introduced during transfusion is rapidly metabolized and excreted. The amount of citrate administered with 500 c.c. of blood is harmless to the adult. When massive transfusions are given in a short period of time, sodium citrate may accumulate in the blood stream, so that signs of hypocalcemia may result, namely, a drop in blood pressure and tetany. This may happen when adults with massive hemorrhage require more than a liter of blood. If 10 c.c. of a 10 per cent solution of calcium gluconate are injected slowly intravenously after every 1,000 c.c. of citrated blood, hypocalcemia may be prevented. When performing exchange transfusions on erythroblastotic babies, some transfusionists inject 1 c.c. of 10 per cent calcium gluconate after every 100 c.c. of citrated blood; others meet the problem by removing part of the citrated plasma from the blood to be used for the transfusion.

Intramedullary Transfusion

In adults, bone marrow transfusion is made through the sternum. In infants and small children where the sternum is too thin, the tibial route is used. The Committee believes that the intramedullary route for ordinary transfusions is not recommended, because of the danger of fat embolism, especially in children. The procedure has resulted in osteomyelitis, and fractures of the tibia. Intramedullary transfusion has its main application in instances of extensive burns or in patients with skin diseases, which makes intravenous therapy difficult.

Other Routes

Transfusion into the longitudinal sinus in inexperienced hands may be dangerous because the blood may be injected extradurally. Nobody any longer advocates the use of intraperitoneal or penile routes.

How to Protect the Blood Donor

If a donor gives blood too frequently, there is likelihood of secondary anemia, a danger greater in women than in men. Donors should not be permitted to donate a pint of blood more often than every 6 weeks or until the blood attains a hemoglobin concentration of at least 12.5 gm. per 100 c.c., or a specific gravity of 1.053 or higher.

A sterile needle, preferably disposable, should be used when obtaining blood for hemoglobin concentration to avoid transmission of hepatitis virus.

Fainting.—Donors often faint when blood is taken or when they see other blood taken. Aside from the psychic aspect, the cause is sudden reduction in blood volume. The incidence of fainting can be reduced by screening out unsuitable donors by physical examination to exclude those with low blood pressure or a low hemoglobin level, or with a small body size. A donor who has been without food for a long time or who makes his donation after coming off a night shift may be a candidate for fainting. They should be given

a light snack before taking their blood. After the donation, the donor should be kept in a supine position until he has apparently recovered. The nervous donor should have his attention diverted from the procedure by pleasant conversation. The room should be light and dry and smoking should not be permitted in it or in the resuscitation room. On hot days, the donors may be given some isotonic sodium chloride solution before the bleeding. If the donor faints, keep the head low, loosen the clothing, and provide with fresh air. In rare cases intravenous infusions of sodium chloride may be required.

Syncope occurs sometimes after the donor has left the hospital. He may fall and lacerate his scalp or even fracture his skull, or become involved in a serious accident if he falls in the street. Donors involved in hazardous occupations should be advised not to return to work for at least 12 hours.

Thrombosis and Infections.—In rare cases, thrombophlebitis or abscess formation has occurred at the site of the puncture. It is wise for the blood bank physicians to protect themselves with suitable insurance to prevent a lawsuit.

Donation of a pint of blood by a healthy adult is safe.

Preparation of Blood Diagnostic Sera

Blood grouping tests are possible only when potent and specific diagnostic sera are available.

Men are used more often than women for the preparation of diagnostic sera. No Rh-negative woman should be immunized with Rh-positive blood to prepare anti-Rh sera if there is any chance of her becoming pregnant later on. Similarly immunization of a group A woman against agglutinin B or vice versa might cause obstetric complications. More common sera, such as anti-**A**, anti-**B**, and anti-**Rh₀**, can be prepared by immunization of male volunteers, but this technic is not applicable to weaker factors such as **rh'**, **rh''**, **hr''**, *Kell*, and *Duffy*. To prepare anti-**A** and anti-**B** sera, a number of different immunization procedures are used.* Intravenous injection of blood group specific substances prepared from horse and pig stomach carries the possibility of anaphylactoid reactions in allergic subjects. This can be avoided by using deproteinized preparations and by administering them intramuscularly instead of intravenously. Some workers also use human blood to prepare anti-**A** and anti-**B** sera. Some subjects complain of pain along the course of the vein during the injection, or have a mild rise in temperature later on. The former can be avoided by diluting the blood with sodium chloride and injecting it more slowly, the latter by having the donor take 5 grains or 0.32 Gm. of acetylsalicylic acid at the time of the injection or by reducing the dosage. Look out for the danger of homologous serum hepatitis.

Before injecting blood into any volunteer, explain the purpose. The sensitized Rh donor should be given a suitable identification card. He should be warned that only Rh-negative blood should be used for any transfusion he may require in the future. A signed release should be secured from the donor.

*Wiener, A. S., Samwick, A. A., Morrison, M., and Cohen, L.: *Exper. Med. & Surg.* **11**: 267, 1953.

Occasionally, volunteers immunized against the Rh factor have developed antibodies against other antigens, most frequently agglutinin M. This can be avoided by testing all subjects for the M-N types, and using only type N, Rh-positive blood for Rh-negative donors of type N.

Physicians are urged to enlist the cooperation of patients whose plasma contains rare blood group antibodies, so that their blood can be used for the preparation of diagnostic sera. Insurance companies specialized in malpractice insurance can aid the work by providing riders on policies of physicians specializing in this field.

Every hospital should have one or more qualified individuals responsible for the transfusions performed there. These should see that the residents are properly trained to perform transfusions, and should be available to advise and assist them when problems of unusual difficulty arise. When nurses or technicians are used in the blood banks for blood withdrawal, this should be under the direct supervision of a qualified physician.

CHAPTER VI

GASTRIC ANALYSIS

GASTRIC CONTENTS

The clinical laboratory is concerned frequently with the determination of the chemical analysis of so-called "gastric contents." "Gastric contents" in this sense means material which remains in the stomach one hour after a classical test meal has been administered. The test meal which has been in use for many years is the so-called "Ewald Breakfast," later to be described. The purpose of placing a sample meal in the stomach is to determine after one hour just how gastric physiology has taken place during this period. Normal gastric digestion is at its height one hour after the administration of the meal.

Reviewing the physiology of gastric digestion, it is known that the secretion of gastric juice begins soon after food is placed in the stomach. It is a transparent, light-colored, yellow fluid which is acid in reaction and contains about 1 per cent of solids. The specific gravity of gastric juice is very low, varying from 1.001 to 1.010. The principal phenomenon that goes on in gastric digestion is the splitting of the protein constituents of food by pepsin in the presence of hydrochloric acid. The action of rennin on milk is also of importance. It is to be noticed that previously emulsified fats are acted upon by lipase, which is a fat-splitting ferment. Pepsinogen and renninogen are also secreted by the gastric glands and are converted into pepsin and rennin by the action of hydrochloric acid. Hydrochloric acid combines loosely with the proteins and is called "combined" hydrochloric acid. That part of hydrochloric acid which is formed after the proteins have been converted into acidmetaprotein is designated "free" hydrochloric acid.

At the time the gastric contents are removed, namely, one hour after the meal has been taken, normally the contents consist of water, hydrochloric acid, combined hydrochloric acid, pepsin, rennin, mineral salts, acid phosphates, and the remnants of undigested food. It also contains various products of digestion in solution. Under pathologic conditions, these materials are present in greater or less extent and sometimes some of them are absent. Under certain conditions, lactic acid is present. Microscopically are seen structures such as blood, bacteria, and abnormal cells.

FACTS ABOUT GASTRIC SECRETION

The stomach normally secretes hydrochloric acid, pepsin, rennin, and mucin. It is important for the laboratory to assist in estimating the degree and activity of the secretory function. Gastric acidity is an index to the concentration of the protein-splitting enzyme pepsin, and the milk-clotting enzyme rennin. There are two kinds of mucin present in gastric secretion, a soluble mucin which plays an important part in buffering the acid, and, in addition, the glairy mucus that is not concerned with this function.

According to Meakins* the amount of increased gastric secretion is best determined in a fasting state and at this time the normal stomach should contain less than 100 c.c. of more or less opaque liquid which, although acid to phenolphthalein, should not contain more than a low (under 10 per cent) concentration of free hydrochloric acid. Greater quantities than 100 c.c., and particularly if the amount of free hydrochloric acid is high, are significant of hypersecretion. Decreased secretion of acid is of considerable diagnostic importance in organic gastric lesions and systemic diseases and such a decrease even to absence of hydrochloric acid is a common accompaniment of carcinoma of the stomach. However, since it occurs in from 10 to 15 per cent of normal people it cannot be taken too seriously unless substantiated by other evidence of local disturbance. Meakins called attention, further, to lowered hydrochloric acid, or its absence, as a prominent sign in the diagnosis of certain diseases of the blood, particularly pernicious anemia. The presence of free hydrochloric acid practically eliminates the diagnosis of pernicious anemia.

Meakins stated that gastric digestion depends almost entirely upon the presence of pepsin which is active in acid medium, but the determination of peptic activity is laborious and is seldom indicated. He believes that in rare cases where there is an entire absence of acid secretion, determinations of peptic activity may be advisable.

METHOD OF OBTAINING STOMACH CONTENTS

Two kinds of tubes may be used in this technic. One is the Rehfluss tube, the other the regulation semistiff, red rubber tube. Some prefer the former, others, the latter. The Rehfluss tube consists of a small, metal oval tip attached to a very small caliber rubber tube. The tip is designed both for obtaining stomach contents and duodenal contents; i.e., it will slip through the pylorus into the duodenum after a certain period of time with the patient in correct position, lying on the right side. Most operators prefer the first kind of tube.

The tubes are, of course, cleaned thoroughly and then placed in a basin of ice water before use. The patient should be gowned and in a sitting position, and the neck should be free.

The cooperation of the patient is very important. He should be told by the operator just what is expected of him and what is about to transpire. He should be assured of the lack of pain and discomfort, provided he cooperates by keeping his mouth wide open. He should also be told to breathe as naturally as possible, and to "swallow" the tube as soon as he is requested to do so. With the mouth wide open and the head back a trifle, the head fixed in a steady position by the left hand of the operator, the right hand of the operator, without placing any fingers in the mouth, inserts the point of the tube directly in the middle line over the base of the tongue. The operator rapidly passes the tube into the posterior part of the mouth, almost "throwing" it in. The patient is now directed to swallow. At the same time, the tube is pushed along gently and firmly with each swallow. Care must be taken, of course, that the tube, when placed over the base of the tongue, does

*Meakins, J. C.: *The Practice of Medicine*, St. Louis, 1950, The C. V. Mosby Co.

not go into the trachea. This is easily avoided by practice. Above all things, the tube should not be oiled or lubricated since this material often causes the patient to vomit. There are some persons with unduly sensitive posterior pharyngeal mucosae in whom the slightest irritation will cause vomiting. It might be well in these cases to paint the mucosa lightly with cocaine; however, this is seldom necessary. During the entire time that the patient is swallowing, he must breathe regularly with his mouth wide open. Provided there is no obstruction, the tube will glide rapidly into the stomach.

As soon as the tube is in the stomach, as judged by the mark on the tube, the outside end is lowered so that it will be below the level of the end of the stomach; a siphon is thus created; the material will flow out. If there is any difficulty, a clean glass 20 c.c. syringe is attached to the outside end and suction is used. It is sometimes necessary to pull the tube gently in and out so as to remove any blocked food particles which may interfere with emptying the contents. If, in any way, failure occurs in inserting the tube, the patient must be assured that this sometimes happens and is not unusual, and that it is often necessary to try again. The psychological influence of the patient in this procedure is very important. There should be no undue movement on the part of the operator or any signs of concern manifested by any person, so the patient's psyche will in no way be disturbed. The distance from the teeth to the cardiac orifice of the stomach is about 40 cm.

If the unskilled operator has any idea at the beginning of the operation that the tube has gone into the larynx instead of into the esophagus, this idea may be dispelled or confirmed by holding the end of the tube to the ear and listening. If the intake and exhalation of air can be heard, the tube must be withdrawn. The tube does not go into the trachea ordinarily, because the opening quickly closes at the approach of a foreign body of this kind, thus throwing the point of the instrument out in the pharynx. If there is considerable disturbance and severe dysphagia and continued strong convulsive coughing during the beginning of the placing of the tube, this indicates that the tube is in the fossa pyriformes at the side of the larynx and the tube is rolled up in a spiral manner at this point. It must be withdrawn and started again. If it is not taken out immediately, it will suddenly be regurgitated after it is drawn up into the mouth. The principal point in the whole procedure is to start the tube directly in the median line, under the eye of the operator.

As noted before, in cases of abnormal sensitiveness the painting of the pharynx with 1 per cent cocaine is necessary.

After the stomach contents have been removed, the tube should be pinched securely with the fingers and rapidly withdrawn. This pinching of the tube holds any foreign body that may be in the tube securely during the process of withdrawal and thus prevents the dropping of foreign bodies into the posterior pharynx and possible entrance into the trachea.

The stomach contents are received in a clean, sterile 500 c.c. glass beaker.

Another method, instead of passing the tube orally, is to pass a small Rehfuß tube through the nostril, and follow the same precautions as above.

Tubeless Gastric Analysis

Segal, Miller, and Morton¹ advocated a method of determination of the hydrochloric acid content of gastric juice which does not require the passing of a stomach tube. This technic depends upon the power of the hydrogen cation of the free hydrochloric acid of the gastric juice at a pH of 3.0 or less to displace the quininium cation from the quininium-resin indicator compound; the quinine and hydrochloride now formed are rapidly absorbed from the small intestine. Quinine is excreted in the urine, where it appears within 15 minutes of ingestion of the resin. The quinine is readily estimated quantitatively in the urine by a simple method based on its fluorescence in ultraviolet light. Segal's quininium-resin indicator is available as a commercial product under the trade name of "Diagnex."²

THE DIAGNEX TEST FOR ACHLORHYDRIA

This test has been extremely reliable in the detection of gastric achlorhydria. The test is qualitatively reliable for the detection of free hydrochloric acid, but the concentration of the free acid present cannot be accurately predicted on the basis of the present grading system.

Powers, Carballo, and Bolt³ concluded that urinary quininium determinations in 76 patients correlated well with the disease state present, and compared favorably with the tube method of gastric analysis in the majority of cases. The method should prove of value as a screening test in the detection of patients with achlorhydria.

The test is indicated in those patients who are unable to tolerate the standard gastric tube, either because of psychogenic or organic illness which precludes the use of the gastric tube. It is extremely valuable in patients with partial gastrectomy or gastroenterostomies because of the unreliability of the gastric tube method in such cases. However, it must be remembered that, as with the uropepsin determination, the use of this test in differential diagnosis of gastrointestinal lesions is limited. A negative quininium test is strong evidence against the diagnosis of benign peptic ulcer. A 1+ to 4+ reaction is of little diagnostic value in the individual case.

Preparation of the Patient.—

The patient must omit taking vitamin preparations on the day preceding the test day. Issue the following instructions to the patient:

1. Do not eat after midnight.
2. Urinate on arising, and discard the urine.
3. Do *not* eat breakfast. Empty the contents of the capsule in the small packet (of Diagnex) into $\frac{1}{2}$ glass of water, stir, and drink. Drink another $\frac{1}{2}$ glass of water or cup of coffee or tea, *without cream, milk, or sugar*.
4. One hour later, or as soon after the one-hour interval as possible, urinate and save this urine (entire quantity) in bottle labeled "Urine Control."
5. Empty the granules in the large packet into $\frac{1}{4}$ glass of water, stir well and drink. Do not chew the granules which do not dissolve. Fill the glass again one-fourth full with water and drink.

¹Proc. Soc. Exper. Biol. & Med. 74: 218, 1950.

²Prepared by E. R. Squibb & Sons, New York.

³J. Lab. & Clin. Med. 43: 3, 1954.

6. At the end of two hours, urinate and save the entire specimen. Empty the bladder completely. If urination ahead of the scheduled time is necessary, add to that passed at the end of the two hours. Mark this 2-hour specimen "Test Urine."

After step 6, the patient may proceed with breakfast.

Technic.—

No urine must be collected after two hours. If the two-hour specimen does not exceed 300 c.c., the determination is carried out as indicated in the instructions. When the urine volume exceeds 300 c.c., the total volume is measured and a 30 c.c. aliquot of this is tested for quinine without dilution. Corrections for the use of this aliquot are $\frac{\text{total urine volume}}{300} \times \text{quantity of quinine in the aliquot}$. This will give the total quinine in the voided urine.

If the physician prefers, histamine may be used as the gastric stimulant and the Diagnex granules may be administered about 45 minutes after administration of histamine.

Carry out the technic on both the control urine and the test urine.

Dilute the entire quantity of each urine to 300 c.c. with distilled water.

To a 30 c.c. portion of this dilution in a separatory funnel, add 0.5 c.c. of N/2 (0.5N) sodium hydroxide.

Extract with 15 c.c. of ether, shaking only gently to prevent emulsification. If necessary, add a few drops of 95% ethyl alcohol to obtain sharp separation of the two layers.

Remove 8.2 c.c. of the ether layer.

Extract with 5 c.c. of N/10 sulphuric acid, inverting 12 complete times. Let it separate and take 5 c.c. of the bottom layer for the test.

Examine this aqueous extract for fluorescence, using a suitable source of ultraviolet light.

A special small separatory funnel, marked off in appropriate places, may be obtained for this test.* If it is used, proceed as follows:

Pour the urine, previously diluted with distilled water to 300 c.c., into the funnel up to mark I.

Add 0.5 c.c. of N/2 sodium hydroxide.

Add ether to mark II.

Invert the funnel gently 5 or 6 times.

Allow to stand for separation of the layers, adding a few drops of 95% ethyl alcohol if necessary to achieve sharpness.

Drain off and discard the contents of the funnel until the top of the ether layer is at mark III.

Add N/10 sulphuric acid to mark IV.

Shake about 10 times.

Allow the layers to separate.

Drain off 5 c.c. of the lower layer for the fluorescence examination.

Measurement of Fluorescence.—

If a photoelectric fluorophotometer is available, the urinary quinine level may be estimated directly from a previously determined standard curve.

If other means of ultraviolet irradiation are used, such as the Menlo Fluoretor,† the Blak-Ray Lamp, Model X-4,‡ or the lamp made by U.V. Comparator,§ estimation must be made by visual comparison with standard solutions containing known amounts of quinine. Since such quinine solutions are of only limited stability, they should be made fresh on the day of use. If a lamp of the Blak-Ray type is used, the observation should be made in a dark room.

*Will Corporation, Rochester 3, N. Y., supplies the separatory funnel.

†Made by Menlo Research Laboratory, Menlo Park, Calif.

‡Made by Ultra-Violet Products, Inc., South Pasadena, Calif.

§710 N. Stricker St., Baltimore, Md.

Standard Solutions.—

Standard solutions may be prepared by using Squibb Diagnex standard tablets.

Each tablet contains quinine hydrochloride equivalent to 1.5 μg of quinine base. The series of standard solutions is made by dissolving 5 of these tablets in a volume of 25 c.c. of N/10 sulphuric acid and diluting with N/10 sulphuric acid in 6 separate test tubes according to Table 129.

TABLE 129

VOLUME OF SOLUTION	AMOUNT OF N/10 SULPHURIC ACID TO BE ADDED (TO MAKE 5 C.C.)	AMOUNT OF QUININE IN STANDARD	EQUIVALENT TO	AMOUNT OF QUININE IN URINE
1. 5.0 c.c.	0.0 c.c.	1.5 μg	=	30 μg
2. 4.15 c.c.	0.85 c.c.	1.25 μg	=	25 μg
3. 3.33 c.c.	1.67 c.c.	1.0 μg	=	20 μg
4. 2.5 c.c.	2.5 c.c.	0.75 μg	=	15 μg
5. 1.67 c.c.	3.33 c.c.	0.5 μg	=	10 μg
6. 0.83 c.c.	4.17 c.c.	0.25 μg	=	5 μg

Or the standards may be made as follows:

Prepare a **stock solution of quinine sulphate** by dissolving 12 mg. of quinine sulphate in 100 c.c. of N/10 sulphuric acid in a volumetric flask (1 c.c. = 0.1 mg. quinine). The stock solution keeps indefinitely, but fresh standards for comparison must be prepared every few days.

Fresh standards are prepared by diluting 0.3 c.c. of the stock solution with N/10 sulphuric acid to a volume of 15 c.c. This solution contains 2 μg of quinine per c.c.

Place in 6 separate test tubes and dilute with N/10 sulphuric acid as in Table 130.

TABLE 130

VOLUME OF SOLUTION (2 μg QUININE PER C.C.)	AMOUNT OF N/10 SULPHURIC ACID TO BE ADDED (TO MAKE 5 C.C.)	AMOUNT OF QUININE IN STANDARD	EQUIVALENT TO	AMOUNT OF QUININE IN URINE
1. 0.75 c.c.	4.25 c.c.	1.5 μg	=	30 μg
2. 0.62 c.c.	4.38 c.c.	1.25 μg	=	25 μg
3. 0.5 c.c.	4.5 c.c.	1.0 μg	=	20 μg
4. 0.37 c.c.	4.63 c.c.	0.75 μg	=	15 μg
5. 0.25 c.c.	4.75 c.c.	0.5 μg	=	10 μg
6. 0.12 c.c.	4.88 c.c.	0.25 μg	=	5 μg

Interpretation.—

The fluorescence of the control sample of urine should first be determined. If the result shows a fluorescence corresponding to 15 μg or more of quinine, the entire test must be disregarded. Report that the patient is excreting excessive amounts of blank fluorescent materials and that the test will have to be repeated after a week, during which intake of the interfering materials, such as quinine or related drugs, the B complex vitamins, or the steroid compounds, is to be eliminated.

If the result on the urine control corresponds to 5 to 15 μg of quinine, the findings on the test urine sample may be interpreted by the method outlined below. However, the results should be corrected for the fluorescence found in the control. This may be done by subtracting the amount of fluorescence seen in the control from the test sample. If the amount of fluorescence of the

urine control corresponds to less than 5 μg of quinine, it may be ignored, and the findings on the test urine sample may be interpreted on the basis of Table 131.

When the total for the urine is within the range of 15 to 25 μg the test should be repeated, but not for 5 to 7 days. A second result in the 15 to 25 μg range means that, while the case is not definitely one of hypoacidity, the possibility of hypoacidity is not ruled out. If the results of this second test are uncertain, the physicians may wish to do other studies such as gastric analysis and intubation to determine achlorhydria. Moreover, it may be advisable for him to use intubation to confirm his findings in every case until facility has been gained in the use of the Diagnex method.

In order to determine the presence or absence of free gastric hydrochloric acid, results on the test urine samples may be interpreted according to Table 131.

TABLE 131

MICROGRAMS OF QUININE OBSERVED IN URINE SAMPLE	FREE GASTRIC HYDROCHLORIC ACID
30 or more	Present
25 or more	Present
About 15	Absent
15 or less	Absent

NOTE: Use only distilled water and solutions which are stored in glass-stoppered bottles; prolonged contact with rubber is particularly to be avoided.

The ether should be of anesthetic grade, preferably from recently opened containers.

The reagents should be checked periodically to establish that they have not become contaminated or undergone any change which might contribute to fluorescence.

If a single urine specimen exceeds 300 c.c., transfer 300 c.c. to a flask and prepare 30 c.c. of this amount as described above, without diluting. If the amount of quinine in this sample is above 25 μg , further examination is unnecessary. If it is less than 25 μg , transfer the remaining urine above 300 c.c. to another flask, dilute to 300 c.c., and prepare for examination in the usual manner. Add the results of both examinations to obtain the total amount of quinine in the urine sample.

TEST MEAL EXAMINATION

The usual method of examination of the stomach contents is one examination obtained one hour after a test meal.

Test Meals

Test meals are given to stimulate secretion of the stomach with food. It can be stimulated with various foods, but for the sake of obtaining uniform results, certain standard test meals have been adopted.

Test meals are given in the morning because the stomach is usually empty at this time. If there is reason to believe the stomach will not be empty in the morning, it is well to wash it with water the evening before.

1. **Ewald's test breakfast** consists of 40 grams of bread (one roll or two slices of bread) and 400 c.c. of water, or weak tea without cream or sugar. It should be well masticated.

2. **Dock's test breakfast** is the same as the Ewald breakfast except that a shredded whole wheat biscuit is substituted for the bread. This substitution is carried out because the Ewald test meal introduces, with the bread, a variable amount of lactic acid and numerous yeast cells, which are completely eliminated by the shredded wheat meal. The shredded wheat biscuit contains no lactic acid.

3. **Boas' test breakfast** consists of a tablespoonful of rolled oats in a quart of water, boiled to one pint, with a pinch of salt added. This should be withdrawn in forty-five minutes to one hour after introduction. It does not contain lactic acid. When this meal is used the stomach should always be washed with water the evening before.

4. **Riegel's test meal** consists of 400 c.c. of bouillon, a broiled beefsteak (about 150-200 gm.) and 150 gm. of mashed potato. It must be thoroughly masticated, otherwise the tube may be occluded when attempt is made to withdraw the meal.

5. **Fischer's test meal** is similar to the Riegel, consisting of an Ewald breakfast plus one-fourth pound of lean, finely chopped Hamburg steak, broiled and lightly seasoned. The Fischer meal and the Riegel meal may be removed in three to four hours. They give higher acidity values than the Ewald breakfast.

6. **Histamine test** is a test which has for its object the demonstration of the ability of the stomach to secrete free hydrochloric acid under the maximum amount of stimulation. It should be done as an initial test if pernicious anemia is suspected. It should also be done as a control on any patient showing achlorhydria or hypochlorhydria with the Ewald test meal. In other words, if the gastric analysis shows an achlorhydria or hypochlorhydria after using this powerful stimulating agent, the results are much more significant than the lowered value for hydrochloric acid or the absence of hydrochloric acid after an Ewald meal. This is administered only on order of a physician.

The test should be performed with the patient under as nearly a basic condition as possible. Remove the stomach contents of a fasting patient by means of a Rehfuess tube. Then administer histamine hydrochloride or histamine phosphate hypodermically. The usual dose is 0.1 mg. per kg. of body weight. Gompertz and Cohen¹ recommend a total dose of 0.25 mg. This is the standard dose of histamine but the actual dose of histamine phosphate equivalent to 0.1 mg. of histamine is 0.19 mg. for each 10 kg. This can be most advantageously administered by injecting 0.25 c.c. of a sterile 1:1000 solution of histamine subcutaneously. Completely aspirate the stomach contents at 30-minute intervals from the time of injection, and determine the volume and total acidity of the samples. The free hydrochloric acid is the same as the total acidity.

7. **Alcohol Test of Gastric Function.**—The use of alcohol with phenolphthalein added as an indicator has been suggested as a substitute for test meals. The technic is to have the patient swallow 49 c.c. of a 7% solution of

¹Gompertz, L. M., and Cohen, W.; *Am. J. M. Sc.* 177: 59, 1929.

alcohol to which has been added 1 c.c. of 0.1% phenolphthalein and 90% alcohol. Determine the percentage of the dye in the stomach contents withdrawn from fasting stomach, by colorimetric methods. It is believed by some that the amount of dilution of the hydrochloric acid may be calculated and that the actual volume acidity of gastric juice may be obtained by this method. It is doubtful whether or not this test may be relied upon because other substances, such as duodenal contents, saliva, etc., may dilute the contents and combine with hydrochloric acid to change the dilution figure.

✓ Examination of the Stomach Contents

Preliminary Survey.—

Volume.—Normal stomach yields about 20 to 50 c.c. This may be more or less, pathologically.

Color.—Normal is colorless. It may be green from bile. Blood is characteristic when present. Color may be altered by blood or drugs.

Consistency.—Normally it is clear. It may contain mucus or undigested food particles.

Odor.—Normally odorless. In disease the odor is sour or rancid. Watch for the odor of drugs.

Sediment.—Normally none. Pathologically, pieces of mucus, food remnants, blood clots, tumor particles.

Starch.—Add a drop of Gram's iodine to the gastric contents. If starch is present, it will turn blue, if undigested. If partially digested, it will turn red.

The *reaction* of gastric contents is acid in health and in nearly all pathologic conditions. It may be neutral in some cases of gastric cancer and marked chronic gastritis, or when contaminated by a considerable amount of saliva.

A small amount of mucus is normally present, but large amounts point to chronic gastritis.

Bile is seen in very minute particles as the result of excessive straining while the tube is in the stomach. Large amounts are rarely found but if they are found, it indicates obstruction in the duodenum.

The Chemical Examination of Gastric Contents

Routine examination means a qualitative test for free hydrochloric acid and organic acid, and quantitative estimations of total acidity, free hydrochloric acid, and sometimes combined hydrochloric acid. In routine work qualitative tests are performed before quantitative tests are begun.

Topfer's Test for Free Hydrochloric Acid

(a) Qualitative.—

Reagents.—

Topfer's Reagent.—

Dimethylaminoazobenzol	-----	0.5 gm.
95% Alcohol	-----	100.0 c.c.

Technic.—

Place a few drops of gastric juice in a test tube. Add one drop of Topfer's reagent. A bright red color will appear if free hydrochloric acid is present. Organic acids produce a red color, but it is less brilliant.

(b) Quantitative.—**Reagents.—**

Topfer's Reagent (above).

N/10 Sodium Hydroxide (page 25). This may be prepared by diluting N/1 solution of sodium hydroxide 1:10.

To about 50 c.c. distilled water in a 100 c.c. volumetric flask add 10 c.c. N/1 sodium hydroxide. Dilute to 100 c.c. with distilled water.

Technic.—

Place 10 c.c. gastric juice in a casserole. Add 1 drop of Topfer's reagent. A bright red color develops if free hydrochloric acid is present.

Place N/10 sodium hydroxide in a buret. Add the sodium hydroxide from the buret drop by drop to the solution in the casserole until the red color is replaced by a canary yellow. Stir constantly during the addition of the sodium hydroxide.

Read from the buret the number of c.c. of sodium hydroxide used. Calculate the number of c.c. of sodium hydroxide required for 100 c.c. of gastric juice. This gives the degree of acidity.

Example.—

2 c.c. of N/10 sodium hydroxide were used for 10 c.c. gastric juice. Ten times 2 c.c., or 20 c.c., would be required for 100 c.c. gastric juice. The degree of free hydrochloric acid is, therefore, 20.

Normal free hydrochloric acid is 20 to 40 degrees.

To change the degree of acidity to percentage, multiply by 0.00365.

It is sometimes advantageous to determine the amount of hydrochloric acid deficiency in cases of achlorhydria. To do this test, place 10 c.c. gastric contents in a casserole, add 2 drops of Topfer's reagent, and titrate with N/10 hydrochloric acid until the first red indicative of free hydrochloric acid appears. Calculate the amount of N/10 hydrochloric acid required to neutralize 100 c.c. gastric contents; this figure represents the degree of hydrochloric acid deficiency. This is not a routine test, and is useful only in those cases in which hydrochloric acid therapy can be used to bring the hydrochloric acid deficiency back to normal.

Total Acidity

The total acidity comprises free hydrochloric acid, loosely combined hydrochloric acid, acid salts, and organic acids such as lactic acid, butyric acid, and amino acids.

Reagents.—**1% Alcoholic Phenolphthalein.—**

Phenolphthalein	1.0 gm.
95% Alcohol	100.0 c.c.

N/10 Sodium Hydroxide (page 25).

Technic.—

Place 5 c.c. unfiltered gastric contents in a casserole. Add 2 drops of 1% alcoholic phenolphthalein.

Have a buret filled with N/10 sodium hydroxide. Add the sodium hydroxide from the buret a drop at a time to the mixture in the casserole, stirring constantly, until the mixture remains a deep pink color. This is the end point. Read from the buret the number of c.c. of sodium hydroxide used. Calculate the number of c.c. of sodium hydroxide required for 100 c.c. gastric contents. This gives the degree of total acidity.

Example.—

If 3 c.c. N/10 sodium hydroxide were used to neutralize 5 c.c. of gastric contents, multiply 3 c.c. by 20 = 60 c.c., or the degree of total acidity in 100 c.c. of gastric contents. Normal degree of total acidity is between 40 and 60 to 70.

Combined Hydrochloric Acid

Reagents.—

N/10 Sodium Hydroxide (above).

1% Sodium Alizarine Sulphonate Solution.—

Sodium alizarine sulphonate	-----	1.0 gm.
Distilled water	-----	100.0 c.c.

Technic.—

Fill a buret with N/10 sodium hydroxide.

Place 10 c.c. unfiltered gastric contents in a casserole.

Add 3 drops of sodium alizarine sulphonate solution.

Add the sodium hydroxide from the buret to the solution in the casserole, a drop at a time, stirring constantly, until it becomes a permanent violet color. This is the end point. Read from the buret the number of c.c. of sodium hydroxide used. Calculate the amount required for 100 c.c. to obtain the degree of uncombined acids. Subtract this amount from the degree of total acidity obtained as above. This gives the degree of combined hydrochloric acid.

Example.—

Total acidity was 60 degrees. It required 4 c.c. N/10 sodium hydroxide to neutralize 10 c.c. of gastric contents.

4×10 gives 40 c.c. of N/10 sodium hydroxide required for 100 c.c. of gastric contents, or the degree of all acids except the combined hydrochloric acid.
 $60 - 40$ equals 20 degrees of combined hydrochloric acid.

Normal combined acidity is 10 to 15 degrees.

Lactic Acid

Lactic acid is not found normally in gastric juice. It may be present after ingesting certain foods; for example, sour milk or foods prepared with it. If emptying of the stomach is delayed, or if the secretion of hydrochloric acid is low, lactic acid may be formed from fermentation of carbohydrates by such lactic acid forming organisms as the Boas-Oppler bacillus. This is a common finding in advanced carcinoma of the stomach.

Reagents.—

1% Carbolic acid.—

Liquefied carbolic acid	-----	1.0 c.c.
Distilled water to make	-----	100.0 c.c.

10% Ferric chloride.—

Ferric chloride	-----	10.0 gm.
Distilled water to make	-----	100.0 c.c.

Technic.—

To 15 c.c. of 1% solution of carbolic acid in a test tube add 10% ferric chloride until an amethyst color is produced. Usually 1 or 2 drops is enough.

Add a few drops of unfiltered gastric contents.

A canary color indicates lactic acid.

Kelling's Method

Fill a test tube with distilled water.

Add 2 drops of 10% ferric chloride. Mix.

Divide the contents in the test tube into two parts.

In the first half, place 1 c.c. filtered gastric juice.

If lactic acid is present, a deep yellow color develops. Compare this color with the color of the control tube (distilled water plus ferric chloride).

Strauss' Method

Place 5 c.c. filtered gastric juice in a small separatory funnel.

Add 20 c.c. ether. Hold the stopper in tightly, and shake thoroughly.

Allow to stand in an upright position until the ether separates.

Allow the bottom fluid to run out. Retain the upper 5 c.c. of ether.

Add to this ether extract 20 c.c. distilled water and 2 drops of 10% ferric chloride solution.

Shake gently.

A slight green color indicates the presence of 0.05% lactic acid. An intense yellowish green color indicates the presence of 0.1% lactic acid.

Reagent.—**Uffelmann's Method**

Add 3 drops liquid carbolic acid to 3 drops of 10% ferric chloride. Dilute with distilled water until an amethyst color is produced.

Technic.—

To 50 c.c. ether, add 5 c.c. filtered gastric juice. Shake thoroughly for ten minutes.

Collect the ether by means of a separatory funnel, or a dropper pipette.

Evaporate to dryness. Add to the residue 5 c.c. distilled water.

Add the dissolved residue to Uffelmann's reagent.

A canary yellow color indicates the presence of lactic acid.

Fractional Method of Gastric Analysis

This method possesses the advantage of emptying and washing the stomach before any test meal is given. A second advantage is that specimens are withdrawn at frequent intervals; this tends to show gastric physiology step by step.

Technic.—

The patient presents himself in the morning without breakfast. He is instructed to eat or drink nothing after the previous evening meal.

At 9:00 A.M. a Rehfuß tube is placed in the stomach. The stomach is then aspirated with a syringe so as to remove all the contents.

After all the contents are removed, the stomach is washed with 100 c.c. of warm water and the washing is continued until clear fluid is aspirated.

The tube is removed and an Ewald test breakfast is now given. This must be thoroughly masticated.

The tube is now reinserted and at fifteen-minute intervals 5 c.c. of the stomach contents are aspirated. This should be carried out during two hours, at which time the stomach should be thoroughly empty. The tube is now removed.

Each of the 5 c.c. portions is examined and also the fluid taken from the fasting stomach. Examinations are made for total acidity, free hydrochloric acid, and lactic acid. In addition, observations should be made concerning the appearance of bile, blood, etc. The emptying time of the stomach is also computed by judging the disappearance of starch from the specimens, indicating that the starchy material of the test meal has all passed into the duodenum.

Normally, the free and the total acidity fall abruptly from a high figure in the case of the resting gastric juice, say 20, down to almost nothing at the end of the first fifteen minutes. From this time on, the free and total acidity rise until one and one-half hours have passed, and it is up to 40. After this time, the values fall until the end of the two hours. The free and total acidity figures are reduced, due to the regurgitation from the duodenum at this time. This is confirmed by the fact that although the acidity falls, the total chlorides increase, indicating that acid is still being secreted although it is being neutralized by the alkalized regurgitation.

The fractional test meal is important in differentiating ulcers of the duodenum, pyloric end of the stomach, and ulcer of the body of the stomach; it is also important in the determination of carcinoma of the stomach. The following data with the test are usual findings:

In chronic ulcer of the duodenum, the free hydrochloric acid in fifteen minutes drops from about 25° to practically none, and then rises from fifteen minutes on, so that in thirty minutes it is likely to be at 30° , in sixty minutes at 60° , in one hour and thirty minutes at 50° , in two hours at 55° . At the same time, the total acidity, beginning at 35° , drops in fifteen minutes to 15° , and then gradually rises; so that at the end of forty-five minutes it stands at 70° , in one hour at 75° , in one hour and fifteen minutes at 80° , dropping at the end of two hours to 70° . In ulcer of the pyloric end of the stomach, at the beginning of the test, the free hydrochloric acid, which is absent, begins to rise in thirty-minute intervals from 2° , at forty-five minutes 10° , at one hour 20° , at one hour and fifteen minutes 35° , one hour and thirty minutes 35° , one hour and forty-five minutes 40° and at two hours 50° . The total acidity, in the meantime, beginning at 10° , drops at the end of fifteen minutes to 5° , and then gradually rises in thirty minutes to 20° , and forty-five minutes to 30° , one hour to 40° , and one hour and fifteen minutes to 70° , one hour and thirty minutes to 75° , and then gradually declines until at the end of two hours it is at 60° . In ulcer of the fundus of the stomach, we find no free hydrochloric acid in fifteen minutes, none in thirty minutes, in forty-five minutes 10° , in one hour 25° , one hour thirty minutes 40° , when it gradually drops so that in one hour and thirty minutes it is 25° , and in two hours 20° . In the meantime, the total acidity, beginning at 15° , drops in the first fifteen minutes to 10° and gradually rises, at thirty minutes to 20° , forty-five minutes to 25° , one hour to 40° , one hour and fifteen minutes to 55° , when it remains stationary, and then gradually drops at the end of one hour and forty-five minutes to 40° , and in two hours to 35° .

In carcinoma of the stomach, there is no free hydrochloric acid at any time. The total acidity, beginning at 10° , drops in fifteen minutes to 5° , then gradually rises in thirty minutes to 10° , in forty-five minutes to 12° , in one hour to 15° , in one hour and fifteen minutes to 20° , when it gradually drops so that at the end of two hours it is again at 10° . In all the specimens, blood and mucus are likely to be found.

In pernicious anemia, no free hydrochloric acid is found in any of the specimens. The total acidity begins at about 8° and runs on almost a straight line of 8° to 10° throughout all the specimens. Bile and mucus are likely to be found in all the specimens.

PLATE XXIX.—TITRATION OF STOMACH CONTENTS.

1. Contents With Topfer's Reagent Showing Presence of Free Hydrochloric Acid.
2. End Point in Titration for Free Hydrochloric Acid.
3. End Point in Titration for Total Acidity.
4. End Point in Titration for Combined Hydrochloric Acid.

Acidity in Various Conditions

Achlorhydria.—The continued absence of free hydrochloric acid in the stomach contents is not in itself a disease entity. There are very few diseases characterized by achlorhydria. In these cases additional clinical and laboratory findings will aid in the proper diagnosis. The lack of titratable acidity in some patients is due to bile and duodenal regurgitation which neutralizes the acid output of the stomach. This kind of achlorhydria can be determined by the estimation of chlorides and trypsin in the gastric contents. While no free acid may appear in the first hour, the study of an acid curve which appears after sixty minutes may be helpful. Achlorhydria is found in the following diseases:

1. **Pernicious Anemia.**—There is very seldom any free hydrochloric acid present in pernicious anemia. The ferments, rennin and pepsin, are also absent. The absence of free hydrochloric acid and of the ferments in the gastric contents may be found long before the blood picture becomes characteristic. Even though liver therapy or vitamin B₁₂ may bring about a normal blood count, yet the achlorhydria remains.

2. **Subacute Combined Sclerosis** resembles pernicious anemia. Every person with achlorhydria is a potential case either of subacute combined sclerosis of the spinal cord or of pernicious anemia. Subacute combined sclerosis is symptomatic of pernicious anemia, but may occur in the course of a leukemia.

3. **Sprue**, which resembles pernicious anemia, is always accompanied by achlorhydria.

4. **Gall Bladder Diseases.**—A diseased gall bladder that has lost its function is likely to be accompanied by an absence of or by a great decrease in free hydrochloric acid in the stomach contents. Wohl¹ particularly calls attention to this fact. Others have corroborated his findings, the particular significance of which lies in the following fact: In a patient with symptoms in the upper abdomen, in whom gastric carcinoma has been ruled out and in whose gastric contents no free hydrochloric acid has been found, the gall bladder should be strongly suspected as the etiological factor responsible for the symptoms.

5. **Diabetes Mellitus.**—In certain cases of this disease with lack of appetite, there is absence of or great decrease in free hydrochloric acid. Their symptoms improved when these patients were given dilute hydrochloric acid.

6. **Chronic Gastritis.**—In this condition the acidity may vary from time to time. Gastritis of the fundus tends toward the absence of hydrochloric acid.

7. **Carcinoma of the Stomach.**—Absence of free hydrochloric acid, lactic acid in the gastric contents, occult blood in the stool, defect and slow emptying of the stomach in x-rays, all favor the diagnosis of malignancy. (See remarks on diagnosis of gastric carcinoma by Papanicolaou and Cooper, method of balloon diagnosis of gastric contents, pages 2193 ff.)

8. **Pellagra.**—Achlorhydria is often encountered in this disease:

¹Wohl, M. G.: *Bedside Interpretation of Laboratory Findings*, The C. V. Mosby Co., St. Louis, 1931.

9. **Syphilis.**—According to Marcus, there is always present a gastric sub-acidity, anacidity, or complete achlorhydria in this disease.

10. **Amebic Dysentery.**—Porgess states that in amebic dysentery the gastric contents frequently show achlorhydria.

11. **Achylia Gastrica.**—Here free hydrochloric acid is absent, and the total acidity rarely rises above 10. The gastric enzymes are absent, due to atrophy of the mucosa. No gastric secretion follows the injection of histamine. Normally 0.1 mg. of histamine per 10 kilograms body weight, injected hypodermically, will stimulate gastric secretion.

12. **Miscellaneous Group.**—Hypothyroidism, rheumatoid arthritis, and pulmonary tuberculosis may frequently be associated with achlorhydria.

Hyperacidity

Hyperacidity is a common occurrence. It is found in patients with neuroses, in cases of constipation, and in excessive cigaret smokers. The eating of too many pickles, or of foods rich in condiments, or of excessive amounts of carbohydrates may produce it.

Gastric and duodenal ulcers are frequently found in association with high acidity; however, in about 50 per cent of gastric ulcer cases, the acidity is normal. In duodenal ulcer the high acidity factor is more constant. The point of high acidity is usually reached in from forty-five minutes to two hours after eating the test meal. The degree of gastric acidity helps to determine the degree of activity of the ulcer; thus, when there is a low total acidity, the ulcer is chronic, inactive, as a rule much indurated, or has gone over to the carcinoma phase.

Occult Blood

Benzidine Test.—Prepare about 3 c.c. of a saturated solution of benzidine (special for blood) in glacial acetic acid in a test tube.

Add an equal volume of 3% hydrogen peroxide. Mix thoroughly. Should the solution turn green or blue, it must be discarded.

Fig. 292.—Hemin crystals. ($\times 100$.)

Add a few drops of unfiltered gastric contents and shake.

A green or blue color indicates the presence of occult blood. (See pages 1289 ff.)

Teichmann Test for Hemin Crystals.—

Disintegrated blood must be examined chemically by the hemin test of Teichmann. Mix a small amount of the suspected material with a crystal or two of common salt, or place it on the thin layer of salt formed by slowly evaporating a small drop of physiologic salt solution on a slide. Cover with a cover glass, and run in enough glacial acetic acid to fill up the

space between slide and cover. Warm the slide over a flame for three-quarters to one minute until bubbles arise, adding more glacial acetic acid until a faint reddish brown tint appears. Then let the acetic acid evaporate entirely, and run distilled water in from the edge of the cover glass.

Microscopic examination will show dark brown rhombic plates or columns of hemin if blood is present.

Benzidine Dihydrochloride Test.—Follow the method given on page 84, substituting gastric contents for urine.

Benzidine Test, Method of Levin and Watt¹.—Mix the gastric or duodenal contents thoroughly with an equal volume of distilled water.

Filter through 1 or 2 Whatman No. 5 extra-retentive filter papers to obtain a clear filtrate.

To 3 c.c. of the clear filtrate, add 5 drops of 50% acetic acid and 5 drops of hydrogen peroxide, and shake vigorously.

Overlay the mixture with 0.5 c.c. of 6% alcoholic benzidine solution and rock slightly. The benzidine solution should preferably be 2 or 3 days old.

A positive reaction is indicated by a green ring at the junction of the benzidine solution and the filtrate mixture.

This test can be used for detecting **blood in vaginal washings**. Sterile water irrigation of the posterior portion of the vagina is performed with an Asepto syringe of 10 to 20 c.c. capacity.

Perform the test without filtration, and, if positive, follow by Papanicolaou examination. The test is positive in cases where there are 4 to 6 red blood cells per high-power field.

If urine is to be tested, centrifuge 10 c.c. at 1,500 r.p.m. for 3 minutes, decant the supernatant fluid, and use the sediment.

Add 1 c.c. of water and 3 drops of 50% acetic acid, shake, and add 3 drops of hydrogen peroxide. Shake vigorously.

Overlay the mixture with 0.5 c.c. of 6% alcoholic benzidine solution, and observe for a green ring at the point of contact of the liquids.

If feces are used, emulsify a small portion in distilled water, filter as for gastric contents, and use 3 c.c. of the filtrate, 8 drops of the acetic acid, and 8 drops of hydrogen peroxide before overlaying with the alcoholic benzidine solution.

Bile

Break up a match stick in about 5 c.c. nitric acid (concentrated). Stratify with a few c.c. of gastric juice.

A play of colors will develop at the point of contact if bile is present.

Butyric Acid

Butyric acid is manifested by the rancid, butter-like odor. If a test is desired, boil the gastric contents to accentuate this odor.

If a piece of moistened blue litmus paper is held in the mouth of the tube, the volatile acid reddens it as it escapes during the boiling. Butyric acid also separates as a drop of oil if a piece of calcium chloride is added to it.

Rennin-Renninogen

Rennin is the milk-curdling ferment of the gastric juice. It is derived from renninogen through the action of hydrochloric acid. Deficiency of rennin has the same significance as deficiency of pepsin, and is more easily recognized.

¹Rev. Gastroenterol. 16: 650, 1949.

Test: Neutralize 5 c.c. of filtered gastric juice with very dilute sodium hydroxide solution. Add 5 c.c. of fresh milk, and place in an incubator or in a vessel of water at about 40° C.

Coagulation of the milk in ten to fifteen minutes shows a normal amount of rennin. Delayed coagulation denotes a less amount.

Pepsin*

“**Tests for Identity.**—An aqueous solution of pepsin (1 in 50) is acid to litmus paper. An aqueous solution of pepsin yields precipitates with solutions of tannic or gallic acid and with solution of the salts of many heavy metals.

“On heating a saturated solution of Pepsin in acidulated water to 100° C., it becomes milky or yields a light, flocculent precipitate, and loses all proteolytic power.

“**Technic.**—Mix 25 c.c. of normal hydrochloric acid with 275 c.c. of distilled water. Dissolve 0.1 gm. of Pepsin in 150 c.c. of this acid. Select a hen’s egg, which is not less than 5 and not more than 12 days old and has been kept in a cool place, and immerse it in boiling water during 15 minutes. As soon as the egg has sufficiently cooled to handle, remove the shell and pellicle and all of the yolk and at once rub the albumen through a clean, dry, hair or brass, No. 40 sieve, reject the first portion that passes through the sieve, and place 10 gm. of the succeeding portion in a wide-mouthed bottle of 100 c.c. capacity. Immediately add 20 c.c. of the acid and stir the mixture well with a rubber-tipped glass rod so as to separate thoroughly the particles of albumen from each other. Rinse the rod with 15 c.c. more of the acid and, after warming the mixture to 52° C., add exactly 5 c.c. of the acidulated solution of Pepsin. At once cork the bottle securely, invert it 3 times, and place it in a bath that has been previously regulated to maintain a temperature of 52° C. Keep the bottle at this temperature for 2½ hours, agitating the contents every ten minutes by inverting it once. Then remove it from the bath, pour the contents into a conical measure having a diameter not exceeding 1 cm. at the bottom, and transfer the undigested egg albumen, which adheres to the sides of the bottle, to the measure with the aid of small portions (about 15 c.c. at a time) of distilled water, until the total amount used measures 50 c.c. Stir the mixture well and allow it to stand for half an hour. The deposit of undissolved albumen does not measure more than 1 c.c.

“The relative proteolytic power of Pepsin, stronger or weaker than that just described, may be determined by ascertaining through repeated trials the quantity of the Pepsin solution made as directed in the assay, required to digest, under the prescribed conditions, 10 gm. of boiled and disintegrated egg albumen. Divide 15,000 by this quantity expressed in c.c. to ascertain how many parts of egg albumen one part of Pepsin will digest.

“Preserve in well-closed containers.”

MICROSCOPIC EXAMINATION

To make a microscopic examination, place a drop of unfiltered stomach contents upon a slide, cover with a cover glass, and examine with a low dry and a high dry objective with the diaphragm opening much reduced. If a drop of diluted Lugol’s solution is placed on the edge of the cover glass, it will run under the cover by capillary attraction and will help to bring out certain structures. (See pages 1627 ff. and 1609 ff. for examination of gastric contents for tubercle bacilli.)

Normally, we see starch granules, with an occasional epithelial cell, yeast cell, or bacterium. Starch stains blue with iodine solution when undigested,

*Reprinted by permission from The Pharmacopoeia of the U. S. A., X.

and reddish, due to erythrodextrin, when partially digested. These colors, however, are not shown clearly unless the iodine solution is very dilute.

Under pathologic conditions, we see remnants of food from previous meals, red blood corpuscles, pus cells, sarcinae, and excessive numbers of yeast cells and bacteria.

Fig. 293.

Fig. 293.—Fat globules. ($\times 400$.)

Fig. 294.

Fig. 294.—Starch granules. Squamous epithelial cells.

Fig. 295.—Cholesterol and carbonate crystals; slight amount of calcium bilirubinate pigment. (Photomicrograph of particle in preoperative specimen of gastric lavage.) (From Rafsky: *J. Lab. & Clin. Med.*, June, 1934.)

Remnants of food from previous meals indicate deficient gastric motility. Red blood cells are recognized by chemical tests, preferably the *benzidine* test. Microscopically, the red blood corpuscles retain a fairly normal appearance but are so degenerated at times that only granular pigment is left. The presence of very fresh-looking red corpuscles is highly suggestive of irritation

of the stomach mucosa by the stomach tube. Pus cells are rarely seen in gastric contents although many of them have been seen in cases of gastric cancer. These corpuscles are partially digested, only the nuclei remaining. The nuclei appear as highly refractile bodies.

Swallowed sputum may be present. See pages 1609 ff. and 1627 ff. for examination of gastric contents for tubercle bacilli.

Sarcinae are small spheres arranged in cuboid groups, often compared to bales of cotton. They are easily recognized and stain brown with iodine solution. They are rarely found in cases of gastric carcinoma. A few yeast cells may be found under normal conditions with considerable numbers in retention and fermentation. They stain yellow to brown with iodine solution. The bacteria encountered are not very important except the Boas-Oppler bacillus. It is claimed that this is found in the majority of cases of carcinoma of the stomach and rarely in any other condition. This organism belongs to the *Lactobacillus bulgaricus* type. The Boas-Oppler bacillus is large, 5 to 10 microns long, nonmotile, and arranged in clumps or in zigzag chains. It stains yellow to brown with iodine solution, thus distinguishing it from *Leptotrichia buccalis* which is sometimes swallowed and may be found in stomach fluid.

Crystalline Elements in Stomach Lavage.—Rafsky¹ reported that crystalline elements were present in the stomach lavage of patients with cholelithiasis. In an effort to approximate this finding, this subject was further investigated in a series of patients with and without biliary tract disease. This study was aided by the use of photomicrographs of crystals seen in the stomach lavage before operation, which were compared with photomicrographs of crystals found in the bile and stones removed from the gall bladder and bile ducts at the time of operation.

Seventy-nine patients were observed and grouped as follows:

Group I. Forty-one patients (51.9 per cent) in whom biliary tract disease was suspected from the history, but who were not operated upon.

Group II. Eighteen patients (20.3 per cent) in whom biliary tract disease was suspected from the history, but who were not operated upon.

Group III. Twenty patients (27.8 per cent) who comprised the control group. In these patients there was no history of biliary tract disease.

The method of procedure was as follows: A gastric lavage with warm tap water was performed upon each patient, the lavage being given preferably in the morning, while the patient was still fasting. The lavage water was then collected and examined for crystalline elements. When crystals were present they were usually found in the greyish or brownish red particles or in the mucus.

In the patients in Group I and Group II, the gastric lavage was made in the morning following an attack of biliary colic or gastric disturbances of sufficient severity to disturb the patient's sleep. When the lavage water was obtained under these circumstances, crystalline elements were found more consistently and in larger amounts.

CONCLUSIONS TO BE DRAWN FROM THE EXAMINATION OF GASTRIC CONTENTS

A number of important points and diagnoses are deducible from examination of the gastric contents. First, the emptying time of the stomach is in a measure determined by this examination. If there is considerable fluid or food particles in the gastric contents, it is reasonable to assume that the case is one of pyloric obstruction, probably caused by a malignant condition of the pylorus or some formation with contraction due to a chronic gastric ulcer. The presence of blood in the gastric contents in visible amount is necessarily due to hemorrhage from an ulcer or carcinoma. Due consideration, of course, must be given to the possibility of a small amount of blood sometimes caused by the passage of the stomach tube.

If there is no free hydrochloric acid present after a test meal, we are inclined to think of the following conditions—pernicious anemia, primary hypochromic anemia, and cancer of the stomach. In pernicious anemia there is complete absence of hydrochloric acid, whereas in cancer a small amount may be present at times, although this is rare. In certain persons, with neither cancer nor pernicious anemia, the nervous excitement caused by the passage of the tube may probably suppress the secretion of hydrochloric acid. In such cases the injection of a preliminary drop of histamine will override this suppression due to nervousness and one can obtain an idea of the true condition. If, however, after histamine injection, no free hydrochloric acid is found, this is necessarily a true achlorhydria.

When increased hydrochloric acid is seen in those persons having ulcers, it is due to hypersecretion by the parietal cells of the stomach. That there is a relationship between hydrochloric acid and peptic ulcer is evidenced by the fact that those with histamine achlorhydria virtually never develop either duodenal or gastric ulcers.

In *dilatation of the stomach*, there is evidence of retention and fermentation, with hydrochloric acid diminished. Pepsin may be normal or slightly diminished. Lactic acid may be detected in small amounts, but is usually absent when the stomach has been washed before giving the test meal. Microscopically, we find sarcinae and other bacteria, and great numbers of yeast cells.

In *gastric neuroses*, the findings are variable. There may be normal, increased, or diminished hydrochloric acid, or even entire absence of the free acid. Pepsin is usually normal.

In *chronic gastritis*, free hydrochloric acid may be increased in early cases, but it is usually diminished in well-marked cases, and is often absent in advanced cases. Lactic acid may be present in traces. Pepsin and rennin are diminished in marked cases. The presence of large amounts of mucus is very characteristic of this condition.

In *atrophic gastritis*, or *achylia gastrica*, which is the terminal stage of chronic gastritis, associated with the blood picture of pernicious anemia, there is decrease in, with sometimes entire absence of, free hydrochloric acid and ferments. Total acidity may be down to one degree. Small amounts of lactic acid may be present.

Gastric carcinoma is possibly the most important condition which we have in mind in examination of gastric contents. There is a total absence of free hydrochloric acid and the presence of lactic acid and of the Boas-Oppler bacillus. Exceptions to this have been found where some free hydrochloric acid and no lactic acid have been found in undoubted cases of carcinoma of the stomach. It must be borne in mind, however, that the presence of lactic acid is very strong presumptive evidence of the existence of carcinoma. In gastric carcinoma, we often find blood, especially when the tumor is located at the pylorus. In these cases occult blood is also likely to be found in the stool.

Gastric ulcer is associated with an excess of free hydrochloric acid in about one-half of the cases. In other cases the acid is normal or diminished. The presence of blood is a very significant symptom of ulcer. It is especially important in these conditions to make an examination of the stool for occult blood, taking care, of course, to have the patient on a meat-free diet for four or five days before making the test.

Summary.—Examination of the gastric contents is of greatest value in the diagnosis of gastric ulcer, gastric cancer, and severe anemia of both pernicious and primary hypochromic type. In gastric ulcer, blood, an excess of hydrochloric acid, and perhaps gastric retention are found. In cancer there is very little or no hydrochloric acid, the presence of blood, together with gastric retention and lactic acid if the growth is near the pylorus. Finally, in pernicious anemia and primary hypochromic anemia there will be a complete absence of hydrochloric acid, no blood, no gastric retention or lactic acid.

GASTROSCOPY AS AN AID TO GASTRIC DIAGNOSIS

The following facts were well presented by Deutsch.¹ Gastroscopic study is indicated (1) in x-ray negative dyspepsia, (2) to clarify an indefinite roentgenographic impression or confirm a positive diagnosis of carcinoma, and (3) in all patients with gastric ulcer or polyps.

Gastroscopy can help in distinguishing benign from malignant ulceration of the stomach. In the antrum and middle portions of the stomach, observation of peristaltic waves and segmental tonus changes aids in ruling out an infiltrating rigid neoplastic lesion. Infiltrating lesions in the cardia or fundus show evidence of obstruction at gastroscopy as much as six months before it is detected at x-ray.

Again, positive biopsies have been taken during gastroscopy. Exfoliative cytology, accomplished by scraping with a polyethylene tube under gastroscopic observation, yields a desquamated mucosa and muscularis mucosa which is quickly aspirated, fixed in Formalin, and prepared for cell block.

Attention is here called to the balloon technic of Cooper, described on page 2193 on the exfoliative diagnosis of gastric lesions.

Radiology and gastroscopy are complimentary aids in the diagnosis of diseases of the stomach. It must be remembered that gastric secretion or mucosal folds in tetanic spasm in a very obese patient occur frequently and make mucosal relief studies by x-ray difficult. At gastroscopy these factors are no obstacle to an adequate examination.

¹Deutsch, Emmanuel: *Postgrad. Med.* 16: 413, 1954.

PHYSIOLOGIC DATA ON GASTRIC SECRETION

In addition to the purely chemical tests already outlined, there are a few tests based upon physiologic reactions which are important in diagnosis.

Determination of the Absorptive Power of the Stomach

Conclusions from this test must be drawn very carefully, otherwise errors will be made. All other factors in connection must be considered together with the facts brought out by this test. It is commonly believed that in organic diseases of the stomach, such as carcinoma and gastrectosis, the absorptive power of the stomach is delayed, but in the neuroses, it is not delayed.

Method: The patient, on an empty stomach, takes a 3-grain capsule of potassium iodide and a glass of water. Be sure that the entire drug is taken from the inside of the capsule. From time to time, the saliva is tested for iodides by moistening starch-paper with it and touching with yellow nitric acid. A blue color shows the presence of iodides. Normally, this should appear in about ten to twenty-five minutes after the ingestion of the drug. If it does not appear until after thirty minutes, it may be assumed that the absorptive power of the stomach is delayed. In order to facilitate the performance of the test, prepare starch-paper by soaking filter-paper in boiled starch and drying.

Test for Motor Power of the Stomach

This test is intended to determine how rapidly the stomach contents pass into the intestine. It is an important aid to diagnosis for the reason that intestinal digestion may compensate for insufficient or absent stomach digestion only so long as the motor power of the stomach is good. Gastric motility is imperative. It is deficient in the following conditions: in pyloric obstruction caused by malignant or benign new growths; in pyloric spasm, as in hyperchlorhydria; and in atony of the stomach wall. It is usually associated with gastrectosis and gastroptosis. To detect deficient motor power, we attempt to find food in the stomach before breakfast in the morning; that is, at a time when the stomach should be empty. Give the patient a meal containing such materials as rice puddings with currants or jam with seeds or raisins, and remove it at the end of six or seven hours. If more than 100 c.c. of fluid can be removed with a stomach tube one hour after an Ewald breakfast, it is an indication of deficient motility of the stomach.

EXAMINATION OF THE DUODENAL CONTENTS

Examination of the duodenal contents is primarily indicated to determine whether or not there is an impaction of the bile duct by gallstones. It indicates the presence or absence of inflammation and stones in the gall bladder. This absence of bile in duodenal contents may be due to a gallstone impacted in the duct or to a cancer at the head of the pancreas. If the bile contains pus cells, it is strongly suggestive of acute inflammation of the gall bladder. Crystals of cholesterol and granules of bile pigment may be found. If both of these are present in considerable amounts, it is presumptive evidence that there are stones in the gall bladder.

Method of Withdrawal

The duodenal fluid is obtained by means of a slender, flexible rubber tube, from 3 to 4 mm. in outside diameter, with a perforated metal tip. It is marked with a series of black rings to indicate the distances from the incisor teeth to the cardia, to the pylorus, and to the duodenum. The Rehfuß tube is the instrument of choice.

If the pancreatic ferments are to be studied, give a cup of bouillon a half-hour before the tube is introduced. In most of the duodenal contents examinations, however, a test meal is not used. The patient abstains from food for about twelve hours, taking only occasional sips of water. The tube is inserted into the stomach in the manner described for the stomach tube. Place the patient upon his right side with hips elevated 6 or 8 inches. The movements of the stomach, aided by gravity, carry the metal tip through the pylorus into the duodenum, usually within thirty to forty-five minutes. Fluid begins to drip from the free end of the tube soon after the metal tip has reached the stomach. If it does not do so, siphonage should be started by injecting a few cubic centimeters of warm water. Collect the fluid in portions of about 5 or 10 c.c. in a series of test tubes. The fluid which first appears is from the stomach and may be recognized by its acid reaction. When the tube enters the duodenum, the fluid becomes slightly alkaline and is usually clear, light yellow or colorless, and viscid. If one is in doubt as to whether or not the tube is still in the stomach, give the patient a few swallows of milk, and aspirate a portion of the fluid through the tube. If the milk appears, the tube is still in the stomach. If the flow should at any time be interrupted, inject a few c.c. of warm water. If, after the tube is in the duodenum, the fluid is somewhat cloudy and opalescent, less alkaline and less viscid, this is the result of admixture with stomach fluid which may have passed through the pylorus. Such fluid is to be discarded.

Examination of duodenal fluid should be done as soon after withdrawal as possible since many of its characteristics quickly change. Normally, it is clear, colorless or light yellow, distinctly viscid, and slightly alkaline. Admixture of acid gastric juice causes it to become somewhat cloudy and opalescent. Cloudiness due to bacteria and pus corpuscles may be present in inflammation of the duodenum or biliary passages.

Lyon-Meltzer Method of Duodenal Drainage*

Drainage of the gall bladder by inducing a relaxation of the duodenum, through the introduction into it of a 25 per cent solution of magnesium sulphate, has attracted a great deal of attention. Lyon claims that by adhering closely to his technic many cases of early gall tract disease can be diagnosed from the examination of the duodenal contents. It has been proved, however, that the so-called A-, B-, and C- bile, presumably originating from three different parts of the biliary tract, have no clinical significance. (The A- bile is supposed to originate in the common duct; the B- bile, a dark viscous bile, in the gall bladder, and the C- bile, a golden yellow bile, in the hepatic duct.) Lintz reported a case that has dealt quite a blow to the A-, B-, and C- bile contention. His patient had congenital absence of the gall bladder and yet,

*Wohl: *Bedside Interpretation of Laboratory Findings*, St. Louis, The C. V. Mosby Co.

upon injection of magnesium sulphate, the three typical specimens of bile, including the dark B- bile, which is supposed to come from the gall bladder, appeared. Nevertheless, a careful microscopic examination of duodenal sediments may be of diagnostic value.

According to Jones, bile-stained leukocytes and epithelial cells, when found in any quantity, indicate an inflammatory condition of the biliary tract. It is not possible, though, to determine from the type of cell found in the duodenal sediments the exact level of the inflammatory process. Too much importance should not be attributed to the finding of these cells; they should be regarded merely as confirmatory evidence.

The presence of many crystals of cholesterin, bilirubin, and calcium bilirubinate may be of diagnostic value in cholelithiasis. It has been claimed by Bockus and his associates that the finding of cholesterol crystals and bilirubin calcium pigment in the same bile is pathognomonic of cholelithiasis.

Chemical Examination of Duodenal Contents

(A) Ferments

Estimation of the pancreatic ferments, amylapsin, steapsin, and trypsin, in duodenal contents, gives the same information as their estimation in feces, but is more reliable. Absence of or great decrease in the quantity of one or all of these ferments points to deficiency of the pancreatic secretion or occlusion of the pancreatic duct. Pancreatic fluid from a fistulous tract shows little or no proteolytic activity. The following methods, although not absolutely accurate, give important clinical information.

1. Amylopsin (Pancreatic Amylase) should be studied along with amylase of urine and blood (pages 140, 141, 374 ff.). Carry out the technic for amylase in feces, but use pure duodenal fluid, 5 c.c. of 1% starch, and bring the volume in each tube to 7 c.c. Express the amount of amylase in units (the number of c.c. of 1% starch digested by 1 c.c. of duodenal contents). For example, if the digestion of starch is complete in the tube containing 0.2 c.c. of duodenal fluid, 25 units of amylase are present. According to Myers and Fine, the average is about 40 units, with extremes of 5 and 200 units in different specimens.

2. Steapsin (Pancreatic Lipase) (Myers and Fine).

Place 1 c.c. duodenal fluid in each of two test tubes.

Boil the contents of one tube to destroy the ferments.

Add to each tube 1 c.c. neutral ethylbutyrate, 10 c.c. distilled water, and a few drops of toluol.

Incubate at 38° to 40° C. for twenty-four hours, shaking occasionally. If lipase is present, the ethylbutyrate will be split, the resulting fatty acid giving an acid reaction in the tube which was not boiled.

Add 2 drops phenolphthalein indicator to each.

Titrate to a pink color with N/20 sodium hydroxide.

The index of lipolytic activity is the difference in the number of c.c. of N/20 sodium hydroxide required for the two tubes. According to Myers and Fine, this is 0.3 to 4.3 c.c., averaging 1.5 to 2.

3. Trypsin.—

If the fluid is acid or neutral, render it slightly alkaline with a weak solution of sodium carbonate.

To 5 c.c. of the fluid in a test tube, add 1 gram of fibrin and a few drops of toluol.

Incubate at 38° to 40° C. for twenty-four to forty-eight hours. Tyrosin and tryptophan can be found if trypsin is present. Neutralize the fluid and examine microscopically for

tyrosin crystals. Test for tryptophan by adding very dilute bromin water a drop at a time. If tryptophan is present, a reddish violet color develops, which disappears upon the further addition of bromin.

4. Amylase.—

To 10 c.c. of 1% solution of freshly prepared starch
add 1 c.c. of the pancreatic juice
and 1 c.c. of toluol.

Allow the mixture to digest at 40° C. until duplicates no longer show blue with iodine solution. Place the bottles in boiling water to stop digestion at the same moment.

Dilute the contents to 50 c.c.

Titrate from a buret against 10 c.c. of boiling Fehling's solution, using acetic acid and potassium ferrocyanide to determine the end point.

Ascertain the number of c.c. of digestive mixture required to reduce 10 c.c. of Fehling's solution, which is equivalent to 0.05 gm. of dextrose, or its equivalent of maltose.

If the amount of sugar in the digestive mixture is less than that required to reduce the copper, add a standard dextrose solution, and compute the amount of dextrose equivalent in the juice used.

Amylase values are reported as the number of c.c. of the digestive mixture, which, when made up to 50 c.c., would be equivalent to 0.05 gm. of glucose. Normal values are given above.

5. Lipase.—

Place in a bottle 1 c.c. of the pancreatic juice.

Add 10 c.c. distilled water

and 1 c.c. of neutral ethyl butyrate

and 1 c.c. toluol

and allow to digest at 40° C.

After 24 hours, determine the amount of acidity developed, using N/20 sodium hydroxide aqueous solution, with phenolphthalein indicator. From the amount of sodium hydroxide used subtract the amount of acidity, if any, in the duplicates containing 1 c.c. of juice plus 10 c.c. water and 1 c.c. toluol.

Shake the digestive mixtures ten times during the 24-hour period.

Express the lipase values as the amount of N/20 sodium hydroxide necessary to neutralize the acidity developed. Normal values are given on page 1213.

6. Alkali-protease (Trypsin).—

Dissolve 10 gm. gelatin

in 100 c.c. of 1% solution of sodium fluoride

and color with methyl violet.

Draw this solution into capillary tubing 1 mm. in diameter.

Quickly place the tubing under cold water to solidify the gelatin.

Cut the tubing into 2 cm. lengths.

Place 10 c.c. of the juice in a small bottle.

Close with a perforated cork through which the gelatin tubes can be inserted.

Keep the digestions at room temperature for 48 hours to determine the alkali-protease.

Add 1 c.c. of toluol to each digestive mixture

and enough 0.2% sodium carbonate solution to make the mixture alkaline in reaction.

Express the alkali-protease (trypsin) values in the number of millimeters of gelatin digested. Normal value is 25 to 50.

Quantitative Methods of Determining the Pancreatic Ferments (Einhorn¹)

Principle.—Agar tubes, mixed with albumin, starch, or fat, allow the ferment action to take place in them by osmosis. If the test substances added are colored

¹From Einhorn, Max: *The Duodenal Tube and Its Possibilities*, ed. 2, 1926, F. A. Davis Company, p. 31, by permission of Dr. Einhorn and the publisher.

with indicators, which undergo a change when acted upon, it is easy to ascertain the presence of the ferments, and also to estimate their approximate amount by the volume of tube changes given in millimeters.

Starch Tubes.—

Agar powder -----2.5 gm.
 Starch -----5.0 c.c.
 Distilled water up to 100 c.c.

Rub the starch and agar in a mortar with sufficient water to make a smooth paste, then add the rest of the water. Place in a flask and heat to boiling point. Draw by suction into a capillary glass tube, inside diameter 1.5 mm., which has previously been warmed in the flame. Allow tube and contents to cool. Cut into 2 cm. lengths. Seal at each end with melted paraffin.

Olive Oil Tubes.—

Olive oil -----25 c.c.
 Agar powder ----- 2 gm.
 Aqueous solution of Nile-blue sulphate (1:2000),
 sufficient to make 100 c.c.

Rub the olive oil and agar together. Add sufficient water to make a thin paste. Add the Nile-blue sulphate solution to make the balance of 100 c.c. Then proceed as with the starch tubes.

Hemoglobin Tubes.—

Hemoglobin powder -----1.0 gm.
 Agar powder -----2.5 gm.
 Distilled water sufficient to make 100 c.c.

Rub the hemoglobin with about 10 c.c. of water until it is smooth, then add the agar powder and the balance of the water. Proceed as with the starch tubes.

Keep the agar tubes on ice until ready to use. They retain their efficiency for a month or six weeks, when they begin to deteriorate; they should not be used when they become dry.

Technic.—

Use one each of the starch, oil, and hemoglobin tubes.

Scrape off the paraffin at both ends.

Put vertically into a small bottle containing about 0.5 c.c. of duodenal secretion.

Add 1 to 2 drops of toluol and keep the bottle at blood temperature for from sixteen to twenty-four hours.

Examine as follows:

Take the agar tubes from the bottle, wipe the outside, and inspect. Hemoglobin tubes show a change of appearance due to action of trypsin, with a clearing up of the end part, becoming more or less transparent. Oil tubes manifest bluish appearance at the end because steapsin ferment splits the oil into fatty acids, which produce this color. Measure the lengths of transparency in the hemoglobin tube and of the bluish color in the oil tube in millimeters. Examine the starch tube by pushing out the agar column and dipping it into a weak iodine solution. The portion of starch column remaining colorless indicates the part changed by the amylopsin ferment into sugar. This is expressed in millimeter lengths.

By these tests, the hemoglobin serves to gauge the trypsin, the olive oil, the steapsin, and the starch the amylopsin ferments.

Fractional Examination of the Duodenal Contents.¹—Einhorn recommends a test meal of one cup of beef broth, usually made by putting one bouillon cube

¹Einhorn, Max: Am. J. M. Sc. 156: 817, 1918.

of Armour & Company in one cup of hot water. The duodenal contents are examined first in the fasting condition, then one cup of bouillon is given by mouth, and the duodenal contents are aspirated every half-hour for a period of two hours. This is carried out as follows: Give patient the duodenal tube in the evening after a light supper. Note the length of tube which has entered the buccal cavity before retiring. The tube used is that recommended by Einhorn with three marks, Mark I, Mark II, and Mark III. Mark III should have reached the mouth; if not, the patient is given milk or water and the tube in this way made to go in beyond the III mark before going to sleep. Attach the tube, lying outside the mouth, with a piece of adhesive tape to the cheek. By early morning the capsule end of the tube has usually reached the duodenum.

Einhorn states that in normal cases there was an alkalinity of the duodenal contents of 30, while one-half hour after the bouillon test meal it was 10, then it rose to 20, 25 and ultimately to 30. The ferments were strongest in the fasting condition, while they were weakest one-half hour after the test meal, to increase in strength later on. In pathologic cases the degree of alkalinity of the duodenal contents appeared to be dependent to a certain extent upon the state of gastric secretion. Einhorn states² that cases of hyperchlorhydria showed a lowered alkalinity while cases of subacidity manifested an increased alkalinity. Other factors play a role, chief of which are pancreatic and duodenal juices and the bile. He differentiates four types of alkalinity curves: **type I**—decrease of the alkalinity during the first half hour after the bouillon test meal, then a steady increase; **type II**—increase of alkalinity between one-half and one hour after the bouillon, then slight decrease; **type III**—increase of alkalinity during the first half hour after the bouillon, then slight decrease up to one hour, then again increase to one and one-half hours, thereupon again a decrease; **type IV**—at first a steady increase of alkalinity up to one and one-half hours after the bouillon test meal, then an abrupt descent of the curve, so that at two hours after the bouillon the contents are acid instead of alkaline.

Einhorn³ gives the following four types of reaction in peptic ulcers:

1. Duodenal contents are always alkaline in the fasting state as well as at any time after the bouillon test meal.
2. The duodenal contents are alkaline in the fasting state and at times acid after the bouillon test meal.
3. The duodenal contents are acid in the fasting condition and at certain periods after the bouillon test meal.
4. The duodenal contents are always acid in the fasting state as well as at any time after the bouillon test meal.

Type I represents the normal. In a number of peptic ulcers the abnormal types (II, III, and IV) were found. The severity of the disturbance is least in type II, greater in type III, and greatest in type IV.

(B) Bilirubin

Bile pigment is usually present in the duodenal contents in sufficient amount to impart a tinge of yellow to the fluid. The depth of color is a

²Loc. cit.

³Einhorn, Max: J. A. M. A. 77: 1471, 1921.

useful guide to the amount present. Report as +, ++, +++; that is, a small, moderate, or large amount, respectively. If bile is present, the diagnosis of complete obstruction of the hepatic or common bile duct is ruled out. Its absence does not exclude the possibility of bile reaching the duodenum at some time. .

(C) Urobilin

Urobilin is a derivative of bilirubin. It is doubtful whether or not the former idea of its identity with hydrobilirubin is correct. Urobilin is normally found in the duodenal contents just as it is in urine.

When we find an increase of urobilinogen and urobilin in the duodenal contents, it means the same as an increase of these substances in the stool. The examination of feces and duodenal contents for these ingredients indicates just how much blood destruction is going on. In other words, they are extremely important in the diagnosis of the hemolytic anemias. In the study of anemias in general, when possible, the estimation of urobilin is interesting but not necessarily important.

The most satisfactory clinical method for urobilin is that of Wilbur and Addis, which Schneider applies to the duodenal contents as follows:

Technic.—

To 10 c.c. of duodenal contents add 10 c.c. of saturated alcoholic solution of zinc acetate. Shake well and filter.

To 10 c.c. of the filtrate add 1 c.c. of Ehrlich's reagent. (See page 73.)

Mix and let stand in a dark place for fifteen minutes.

Examine with a spectroscope and dilute with 60% alcohol until the bands of both urobilin and urobilinogen have disappeared exactly as is described for urobilin in feces. Calculate the dilution value for 1,000 c.c. of duodenal contents, remembering that the filtrate used represented 5 c.c. of duodenal fluid. If, for example, the urobilin and urobilinogen bands disappeared when the 10 c.c. of filtrate was diluted to 80 c.c. and to 40 c.c., respectively, then the dilution value of 5 c.c. of duodenal fluid is 16 for urobilin and 8 for urobilinogen; and for 1,000 c.c. it would be 200 times this, or 3,200 and 1,600, with a total dilution value of 4,800.

Schneider found that the maximum for healthy medical students is about 1,000 dilutions, and that urobilinogen is never present. In pernicious anemia and hemolytic jaundice urobilinogen is generally present, the total dilution value usually reaching 3,000 to 5,000. Giffin, Sanford, and Szlapka found a striking decrease following splenectomy, particularly in pernicious anemia.

Schneider used these figures in the following formula, which aims to express the relation between blood regeneration and blood destruction in the form of an index number which he designated as the H-H (hematopoietic-hemolytic) Index:

$$\text{hemolytic) Index: } \frac{Z + Y}{6} = \text{H-H index, } Z \text{ representing the total duodenal}$$

urobilin-dilution value in thousands, and Y the red corpuscle count in millions. Under normal conditions (urobilin dilutions 1,000, red cell count 5,000,000) the index is 1. When hemolysis is very active, it will be above 1 unless counterbalanced by very deficient blood formation. When blood regeneration fails the index will be below 1. Such an index is artificial and arbitrary, but is useful in stressing the importance of considering the ratio of blood formation to blood destruction in the course of an anemia.

Microscopic Examination of Duodenal Contents

Unless the duodenal fluid is examined within a few minutes after it is secured, the cellular elements may be damaged or destroyed by the ferments. The method is the same as for fresh urine. Normally only an occasional leukocyte or epithelial cell can be found. Pathologically these may be present in increased numbers, but no definite diagnostic inferences can be drawn. A great excess of pus corpuscles suggests inflammation of the duodenum or biliary tract. *Strongyloides stercoralis* and *Giardia lamblia* have been found, sometimes in great numbers. Cystic and vegetative forms of *Endamoeba histolytica* have also been found, and in such cases infection of the liver or bile passages is inferred.

Bacteriologic Examination.—At the present time very little of clinical value can be learned from a bacteriologic study. Normally the fluid is sterile or contains only a few gram-positive cocci. Bacteria seen in the direct microscopic examination are mostly dead.

For bacteriologic examination the duodenal fluid is obtained in the usual way, with the following precautions to prevent contamination:

Sterilize the tube by boiling. Slip over the metal tip a gelatin capsule which has been soaked in alcohol for several days. Dip the gelatin-covered tip in thin shellac several times, letting it dry after each coating. Introduce the tube in the usual way. When it has entered the duodenum, the gelatin bag may be removed by forcing in a little air or a few cubic centimeters of sterile water. (See pages 1609 ff. and 1627 ff. for examination of gastric contents for tubercle bacilli.)

Cytologic examination is discussed on pages 2192 ff.

The Value of Protein Nitrogen and Nonprotein Nitrogen Determinations on Gastric Juice

A series of papers has been written by Lay Martin¹ on this question.

Normal nonprotein nitrogen is usually found within certain quantitative limits; the fasting juice in normal cases contains more protein and nonprotein nitrogen than the succeeding ones.

Benign achlorhydria, under stimulation with histamine, showed higher values than those of the normal, but lower than those of gastric carcinoma or of nephritis with marked increase in blood nonprotein nitrogen.

Does the stomach act as an agent for removal of these products of metabolism from the body? Are they reabsorbed in the lower intestinal tract? Are they destroyed or benignly conjugated? Williams and Dick² attempted to answer these questions by establishing standards of normality for intestinal excretions of nonprotein nitrogen products after ingestion of magnesium sulphate. They showed they are quantitatively increased in nephritis.

Withdrawal of Contents and Precipitation of Proteins.—A duodenal tube is placed in the dependent portion of the stomach of a patient who has fasted for fifteen hours, the position of the tube being verified by fluoroscopy. Entire fasting secretion is removed and placed in a refrigerator.

¹Martin, L.: Bull. Johns Hopkins Hosp. 49: 286, 1931. J. A. M. A. 100: 1475, 1933.

²Williams, J. L., and Dick, G. F.: J. A. M. A. 100: 484, 1933.

Gastric juice flow is stimulated by hypodermic injection of histamine (ergamine acid phosphate) in amounts equivalent to 0.005 mg. per kilogram of body weight. Entire flow of gastric juice is collected by continuous siphonage into a narrow container surrounded by ice. All specimens with bile tinge are discarded. After gastric flow stops, all gastric juice is filtered in a refrigerator at 7° C., giving a limpid fluid free of mucus.

Proteins of the gastric juice are precipitated by tungstic acid at pH 3.5. Therefore a protein-free filtrate is obtainable which can be used by methods described for the estimation of amino acid, urea, ammonia and nonprotein nitrogen. Total nitrogen for the whole mixture is determined by the Kjeldahl method. The precipitate is redissolved in alkali and the protein nitrogen determined by the same technic.

Normal Averages.—Protein of the mucus-free gastric juice averaged 22.59 mg. of nitrogen per 100 c.c. of gastric juice.

The nonprotein nitrogen was 25.5 mg. per 100 c.c. of gastric juice.

Amino acid nitrogen averaged 7.22 mg. of nitrogen per 100 c.c. of gastric juice.

Urea averaged 2.58 mg. of nitrogen per 100 c.c. of gastric juice.

Ammonia nitrogen averaged 5.19 mg. of nitrogen per 100 c.c. of gastric juice, far more than the negligible amount in blood, suggesting speculation concerning the purpose of the urea-splitting enzyme appearing in the gastric juice and the gastric mucosa.

Uric acid averaged 1.5 mg. per 100 c.c. of gastric juice.

Accordingly, there are 8 mg. of nonprotein nitrogen unaccounted for.

Results in Different Cases.—In benign achlorhydria, protein and nonprotein nitrogen double that of the control group. Compared with seven cases of pernicious anemia, it was found that there was much more amino acid nitrogen and urea nitrogen in pernicious anemia than in benign achlorhydria with consequent rise in nonprotein nitrogen.

In proved cases of carcinoma of the stomach, protein and nonprotein nitrogen fractions increased from four to six times the normal.

Summary:

1. Normal gastric juice shows rather constant figures for protein and nonprotein nitrogen fractions (amino acid, urea, uric acid, and ammonia).
2. In benign achlorhydrias the amounts increased twofold.
3. In pernicious anemia the same increase was found plus still greater increase in amounts of amino acid and urea.
4. In carcinoma of the stomach with achlorhydria, very large amounts of protein and nonprotein nitrogen were found.

Methods for Determination.¹—

Total nitrogen has been determined for normal gastric juice by the Kjeldahl method.

To obtain a protein-free filtrate, it was necessary to devise a method for the precipitation of these materials from a medium with a normal hydrogen ion concentration around 2; in the achylia it was around 7. Blood proteins

¹Martin, Lay: Bull. Johns Hopkins Hosp. 44: 286, 1931.

are precipitated by tungstic acid according to the method of Folin and Wu at a pH of about 7. This method, when applied to gastric juice, in most cases gives no precipitate. Only when the hydrogen ion concentration has been increased to a pH above 4 is one able to precipitate the maximum amount of protein. Routinely this was done in the following manner:

Technic.—

To gastric juice add one-half the amount of 10% sodium tungstate. As this solution is gradually added, a cloudy precipitate is formed which is reabsorbed as the pH decreases. Two-thirds normal sulphuric acid is then added, drop by drop, until the pH of the solution is brought to about 3.5. From many trials it has been found that this is about the optimal point of the heaviest precipitation. This end point can be recognized by means of Congo red paper which just begins to turn from light to dark blue. The material is then made to any required dilution, usually about 4 to 1. In the achylia, experience has shown that a 6 to 1 dilution is sufficient. Filtration through a Whatman No. 42 filter paper will usually produce a perfectly clear filtrate. If this does not appear at first, refiltering through the same paper will usually bring about the desired result. Standing overnight in a refrigerator will also increase the size of the precipitate particles and make filtration easier.

Biuret Tests.—

Biuret tests done upon filtrates are negative or show so little color that one feels sure that the amount of protein material can have no significant influence on the findings. A comparison of the biuret reaction on the unfiltered and the filtered portion is sufficient to justify the conclusion that, even when this very faint trace of lavender or pink is seen, the amount of protein therein is certainly negligible.

Nonprotein Nitrogen.—The estimation of the total nitrogen on the filtrate is carried out by the usual Folin and Wu nesslerization method. It lies normally between 20 and 48 mg. per cent. In simple achylia, the percentage is higher, up to 30 and 90 mg. per cent. In achylia complicated by carcinoma the figures have been as high as 60 to 150 mg. per cent.

Amino Acids.—The amount of amino acids was determined by the blood filtrate method of Folin. Due to the higher acidity, much more sodium carbonate must be used before the phenolphthalein will impart a permanent pink color to the solution.

Urea.—Urea is determined by first estimating the amount of free ammonia plus the amount of ammonia liberated by the action of urease; from this result subtract the predetermined amount of ammonia.

Ammonia.—Ammonia is determined by two methods: first, unfiltered gastric juice, usually 5 c.c., by the microaeration method of Folin and MacCallum; second, upon the filtrate using the method of Folin and Wu.

Determination of Blood Group by Examination of Gastric Contents. See agglutinin inhibitory tests, Chapter V, pages 1169 ff.
